Gefitinib (Iressa) is a small-molecule inhibitor of the tyrosine kinase portion of EGFR. It works by binding to the ATP-binding site of the tyrosine kinase enzyme. The resulting uninhibited Ras signal transduction cascade is effectively halted by this molecule. The ultimate effect is inhibition of cell growth.

Due to its effects, gefitinib has been evaluated in a number of cancers. It is now approved for use in refractory non-small-cell lung cancer. Its side effect profile is well tolerated. Side effects include rash, nausea, stomatitis, and fatigue.

Erlotinib (Tarceva) is a small molecule that is quite similar to gefitinib. It works like gefitinib to inhibit the tyrosine kinase domain of the EGFR. It displays a similar side effect profile to gefitinib and is also indicated for use in refractory non-small-cell lung cancer. Additionally, erlotinib has been recently approved for use in combination with gemcitabine for the treatment of advanced pancreatic cancer.

### 7.13 Sorafenib and Sunitinib

Multitarget tyrosine kinase inhibitors are an interesting group of protein kinase inhibitors. These agents allow for the inhibition of several different tyrosine kinase enzymes to work synergistically to halt abnormal cell growth. Sorafenib (Nexavar) and sunitinib (Sutent) are examples of two multitarget tyrosine kinase inhibitors.

Sorafenib targets the tyrosine kinases c-KIT, PDGF, VEGF, Raf, B-Raf, and extracellular regulated kinase (ERK). Explanation of the actions of each of these kinases is quite detailed. Inhibition of these tyrosine kinases allows for the simultaneous inhibition of cellular growth, proliferation, division, and angiogenesis. Inhibition of multiple pathways allows for a more effective agent.

Sorafenib has been approved for use in advanced renal cell carcinoma and has been shown to improve progression-free survival [64]. It has also been shown to have activity in other cancers, including hepatocellular carcinoma [65]. The drug is fairly well tolerated with rashes, diarrhea, and hypertension as main side effects.

Sunitinib is another important multitarget tyrosine kinase inhibitor. It works on the tyrosine kinases c-KIT, PDGF, VEGF, RET, and fms-like tyrosine kinase receptor-3 (FLT3). Similarly to sorafinib, this agent's multikinase inhibition causes inhibition of multiple processes integral to the proliferation of malignant cells. The drug is currently approved for use in advanced renal cell cancer. Due to its c-KIT activity, sunitinib has been approved for imatinib-resistant GIST. The drug has also been shown to have activity in a number of other tumors including breast cancer, non-small-cell lung cancer, and neuroendocrine tumors [66]. Like sorafinib, the drug is very well tolerated with skin changes, hypertension, nausea, fatigue, and diarrhea as major side effects.

There are a number of approved tyrosine kinase inhibitors available and in research. Please see Table 14 for more information on some of these agents.

**TABLE 14 Protein Kinase Inhibitors**

| Drug | Approved Uses | Major Side Effects |
|---|---|---|
| Dasatinib | CML | Marrow suppression, edema, headaches, diarrhea |
| Erlotinib | NSCLC, pancreatic cancer | Rash, diarrhea, anorexia |
| Gefitinib | NSCLC | Acne, diarrhea, GI distress, hepatitis |
| Imatinib | CML, gastrointestinal stromal tumors (GISTs) | Edema, nausea, rash, myalgias |
| Lapatinib | Breast cancer | GI distress, anorexia, rash |
| Nilotinib | CML | Cardiotoxicity |
| Sorafinib | Renal cell cancer, hepatocellular carcinoma | Rash, diarrhea, hypertension |
| Sunitinib | Renal cell cancer, GIST | Fatigue, GI distress, hypertension, skin changes, stomatitis |

### 47.7.14 Monoclonal Antibodies

Monoclonal antibodies are essentially antibodies created to target a specific antigen. By doing so, drugs can be made to bind cell receptors and enzymes that mediate growth. Monoclonal antibodies can also be created to target abnormal oncoproteins that are commonly found in malignant cells. Several different groups of these agents have been developed. Some work by targeting and inhibiting tyrosine kinases. Others work by binding and inactivating other integral cellular receptors and enzymes.

Trastuzumab (Herceptin) is one example of a monoclonal antibody that is used for cancer treatment. This drug works by binding to the extracellular HER2/neu receptor. HER2/neu is a tyrosine kinase mediated receptor that is overexpressed in some types of breast cancer. Overexpression of the receptor causes overactivation of a mitogenic signaling pathway involving mitogen-activated protein kinase (MAP) kinases. The resulting effect is promotion of cellular invasion, increased angiogenesis, and prolonged survival. Tumors expressing this abnormality are typically thought to have a worse prognosis due to resistance to standard chemotherapy. By binding and inhibiting the HER2/neu receptor, trastuzumab downregulates effects of the receptor. This results in arresting the cell cycle and suppression of angiogenesis.

Trastuzumab has been noted to drastically change the treatment of HER2/neu-positive breast cancer and is indicated for therapy. This agent shows significant activity in tumors that previously showed poor response to standard chemotherapy. Additionally, this drug is well tolerated when compared to standard chemotherapy. Major side effects include cardiac toxicity, rash, nausea, diarrhea, and myalgias.

Bevacizumab (Avastin) is another monoclonal antibody that inhibits tyrosine kinases. This drug works to target the VEGF. Targeted inhibition of VEGF results in inhibition of angiogenesis. This process is normally vital to tumor growth due to the need for blood supply. Inhibition of angiogenesis essentially causes the tumor to "starve" and it will not be able to grow further or metastasize. Inhibition of this growth factor receptor has shown promise in a number of tumor types. Bevacizumab is currently indicated for use in colon cancer and most recently in breast cancer [67]. It has shown promise in a variety of other cancers, including lung cancer, ovarian cancer, and renal cell cancer. Due to its inhibition of angiogenesis, bevacizumab has been noted to cause problems with wound healing. It has also been noted to cause hypertension, rash, and increased risk of bleeding.

A number of other monoclonal antibodies are used as anticancer agents. Their uses and side effects are noted in Table 15.

**TABLE 15 Monoclonal Antibodies**

| Drug | Approved Uses | Major Side Effects |
|---|---|---|
| Cetuximab | Colorectal cancer, head and neck cancer | Severe rash |
| Trastuzumab | *Her2/neu*-positive breast cancer | Cardiotoxicity |
| Rituximab | B-cell lymphoma and leukemia | Infusion reactions, pulmonary toxicity, fever |
| Bevacizumab | Colorectal cancer | Impaired healing, hypertension, bleeding |
| Gemtuzumab ozogamicin | AML | Marrow suppression, venoocclusive disease, fevers |

### 7.15 mTOR Inhibitors

Mammalian target of rapamycin (mTOR) is a serine–threonine protein kinase that regulates cell growth, proliferation, protein synthesis, and survival [68]. Inhibition of this protein kinase has been a popular mechanism for immunosuppressants. Recently, inhibition of this protein kinase has shown some utility for its use as an anticancer agent.

Temsirolimus (Torisel) is an mTOR inhibitor that has shown its ability as an anticancer agent [69]. By inhibiting mTOR, temsirolimus effectively hinders cell proliferation and angiogenesis. It has shown significant activity in several different tumor types.

Recently, temsirolimus was approved for the treatment of renal cell carcinoma. The side effect profile of this drug is mild and includes bone marrow suppression, rash, weakness, nausea, and diarrhea. The mTOR pathway is integral for growth and angiogenesis in a number of different tumor types. There is hope that temsirolimus will find utility in multiple tumor types due to these effects.

### 7.16 Cancer Vaccines and Immunotherapy

There is existing evidence that suggests that the immune system plays an important role in controlling malignancy. This has been supported by the observation of the regression of cancer in some patients as well as increased cancer incidence in patients who are immunosupressed. In addition, in numbers of tumors including melanoma there is evidence of tumor infiltration by immune cells. Those observations led to the development of several strategies including immunotherapy with cytokines, two of which, interferon and interleukin-2, are available for treatment of renal cell carcinoma and

malignant melanoma. In addition, several vaccine strategies have been developed for the treatment of cancer, however, to date none has been effective enough to be part of cancer patient management outside of a clinical trial. Cells of an innate immune system respond to signals provided by growing tumors that cause induced inflammation and activate innate effector cells with antitumor activity, and stimulate antigen presenting cells and dendritic cells. This leads to migration of the immune cells to the draining lymph nodes and results in triggering adaptive response by B and T lymphocytes. Natural killer cells and T cells produce interferon after activation, which on its own has a tumoricidal activity and stimulates macrophages and dendritic cells to produce interleukin-12. The expansion and activation of natural killer cells can also be accomplished by increased levels of interleukin-2. The use of high-dose interleukin-2 therapy has been shown to induce responses in 16% of patients with metastatic malignant melanoma and 21% of patients with metastatic renal cell carcinoma. Six percent of patients with metastatic kidney cancer or melanoma can be cured with that strategy, even at the metastatic stage of the disease.

A different strategy to enhance immune responses against cancer was the administration of adjuvant agents. Those agents may contain bacterial products such as lipopolysaccharide or CpG oligodeoxynucleotide. (C stands for cytosine, p for phosphodiester, and G for guanine.) containing oligodeoxynucleotides, recognized by Toll-like receptors. In recent years, development of small molecules directly stimulating Toll-like receptors has been also seen. The activation of Toll-like receptors leads to production of pro-inflammatory cytokines and productive interaction between the innate and adaptive immune responses. Those strategies were recently tested in patients with non-small-cell lung carcinoma as was malignant melanoma.

Another very important recent strategy in developing increased immunity against cancer is to suppress activity of regulatory T cells. This strategy had been developed with developing antibodies against the CTLA4 molecule. This strategy has been tested in malignant melanoma and lung cancer with mixed results.

In order to improve visibility of the cancer antigens to immune system, a number of different strategies have been developed, including identification of tumor-specific proteins and the introduction of those proteins either alone or with adjuvant therapies.

In addition, a number of therapies has been developed to stimulate dendritic cells or to "teach" dendritic cells to recognize tumor antigens ex vivo. One of these strategies is cancer cell fusion with autologous dendritic cells, which would allow the enhanced presentation of tumor antigens to other elements of the immune system. One early strategies was isolation from tumor-infiltrating lymphocytes and after ex vivo expansion re-infusion to patients with cancer. Similarly ex vivo expansion of natural killer cells and infusion to patients with leukemia or breast cancer resulted in promising activity.

Genetically modified T cells expressing cytokines have also been used as a strategy to enhance tumor recognition. Recently, a renaissance in interest in developing clinical vaccines has been seen even against solid tumors that were previously thought to have little immunogenic potential, for example, lung cancer, prostate cancer, or brain tumors. In conclusion, there is a multitude of different immunomodulatory and vaccine strategies in development. So far, the proven clinical value has only been provided by interferon and interleukin-2 in patients with renal cell carcinoma and melanoma.

Vaccine strategies are very appealing because they present a possibility of tumor-restricted therapy with limited toxicity suffered by normal organs. As the current knowledge of immune responses to the foreign antigen or mutated self-antigen is being developed, new clinical studies are being designed. This hopefully will lead to clinical introduction of anticancer vaccine strategies in the next several years.

### 7.17 Conclusion

There is a multitude of different agents currently available for cancer treatment. Some agents have quite broad mechanisms of action while others are more specific. In general, it is noted that the agents that have a more specific mechanism of action are typically tolerated better. This is why the molecularly targeted agents have gained so much esteem recently. Despite this, standard cytotoxic chemotherapy does still play a role in the treatment of cancer. In the future we can expect to see more molecularly targeted therapies being developed. These drugs will likely become more tumor specific, thus improving their side effect profile. Standard cytotoxic agents will also continue to be useful. The development of these agents will continue to increase our arsenal of therapies for cancer. The ultimate goal is to develop a treatment regimen that has virtually no side effects, while still effectively irradicating tumor cells. As our knowledge of cancer cell biology increases, we will only find more targets for our drugs. Utilizing the vast array of research tools will facilitate the development of these agents.

## 8 DRUG FORMULATION AND DELIVERY SYSTEMS

The process of finding potential anticancer drugs is often extensive and difficult. When promising agents are eventually found, they must overcome more hurdles. One such hurdle is in regards to how they will be

delivered. Drug solubility, stability, bioavailability, concentration, and local toxicity all play a role in developing appropriate delivery systems for anticancer drugs. In this current day and age, there is a multitude of ways to deliver drugs. Intravenous, oral, sublingual, intranasal, subcutaneous, and even transdermal routes are used to deliver a number of drugs. Anticancer agents are notably cytotoxic agents and often require specific delivery systems. At this point, most anticancer agents are administered intravenously. There is, however, a number of newer agents that are being developed that utilize an oral route. The advancement of drug delivery systems is to thank for these advances. The easiest way to think of anticancer drug delivery is to break it up into several categories: drug formulation, drug delivery systems, drug conjugates, and prodrugs.

### 8.1 Drug Formulation

Drug formulation is the process by which several different chemical compounds are combined with a drug to create the final medicinal compound. The formulation of a medicinal compound can be achieved with several different goals in mind. Currently, the most widely utilized approach in anticancer research is to develop a formulation that keeps the integrity of the drug as "pure" as possible [70]. This essentially means that care is taken to make sure that the mechanism of action of the drug is not changed by the formulation. Another popular approach is to develop a formulation that enhances the drug's effectiveness, either by increasing its effect on the target cells or by minimizing the adverse effect of the drug so that a higher dose may be given.

The first step in formulation is actually preformulation techniques that are used to analyze the chemical structure of the drug. This step is called analytical characterization. Analytical characterization utilizes approaches such as nuclear magnetic resonance (NMR) imaging, mass spectroscopy, differential scanning calorimetry (DSC), X-ray diffraction analysis, and infared spectroscopy [71]. These steps are performed to find information regarding the chemical structure of the compound, as well as to evaluate some of the properties of the compound. Properties such as solubility, drug stability, and molecular size can be determined using these technologies. Once this data is ascertained, further work on formulation of the final drug compound can be more easily achieved.

### 8.2 Solubility

Solubility is a property that is integral in drug formulation. A potential anticancer agent may be useful in vitro, however, if it is insoluble in vivo, it can be useless. There are multiple acceptable solvents available for the delivery of anticancer agents. However, these solvents can come with their own adverse effects. A prime example of this is Cremophor EL [72]. This is a nonionic surfactant that is used to deliver paclitaxel. When it is given intravenously, it can cause severe anaphylactic reactions and over time can cause peripheral neuropathies. When receiving paclitaxel infusions, patients typically have to have the infusion run over a long period of time to prevent anaphylaxis. They often have to be premedicated with antihistamines or corticosteroids to prevent reactions. For this reason, solvents must be carefully selected. Optimally, an anticancer agent will be soluble in a well-tolerated medium, however, events do occur in which an agent is entirely insoluble. In this case further techniques must be employed to aid in solubility. Other solubilization approaches include adjusting the pH, utilizing co-solvent or surfactant systems, creating emulsions, and developing colloidal systems.

If a compound is insoluble using standard solvents, altering the pH is often the first approach to improve solubility. By adjusting the pH, one can change the ionized form of the compound to allow it to have better solubility in the corresponding solvent. When drastically altering the pH, it is important to evaluate the changes in the compound's stability and possible changes in efficacy. It is also important to ensure that the altered pH will not cause the drug formulation to become harmful to the recipient.

Co-solvent and surfactant systems are also commonly used to improve solubility. Common cosolvents used today include dimethyl sulfoxide (DMSO), ethanol, polyethylene glycol (PEG), sorbitol, glycerin, propylene glycol, and *N*-methyl-2-pyrrolidone [73]. An appropriate co-solvent will be miscible with an aqueous solution. This will allow the drug to be dissolved in the co-solvent and then this solution can be dissolved into a water-based solution. Unfortunately, these systems can be difficult to use as minor changes in temperature, pH, or further dilution can cause the compounds to precipitate out of the solution. This can be remedied by the use of surfactant systems. Surfactant systems work by using particles that have polar and nonpolar regions that will essentially reorganize themselves to create micelles in aqueous solutions. These systems are quite beneficial in more nonpolar compounds as the micelles will surround the nonpolar particles with their nonpolar regions, keeping the polar regions on the outer surface of the micelle, thus allowing the micelle to be soluble in water. There are a number of surfactant systems used today including Cremophor EL, pluronic copolymers, and polysorbate polymeric systems.

Emulsions can be utilized to create soluble drug formulations when the compound of interest is highly lipo-

philic. An emulsion is essentially a mixture of two immiscible substances. There are many common emulsions we see in everyday life. These include butter, mild, ream, and mayonnaise. Emulsions work by mixing one substance (sometimes called the dispersed phase) into another substance (the continuous aqueous phase). This "oil-and-water" mixture is usually stabilized by an emulsifier. An example of an emulsion system being researched currently is the paclitaxel vitamin E emulsion (TOCOSOL) [74]. This formulation uses vitamin E, a tocol, which is a large lipophilic molecule. The formulation involved dissolving paclitaxel in vitamin E initially. This lipophilic solution is then homogenized with water, utilizing surfactants as the emulsifying agents. The surfactants utilized are d-alpha tocopheryl polyethylene glycol 1000 succinate (TPGS) and Poloxamer 407. The final product is an emulsion system that consists of three principal components, an inner core consisting of the lipophilic tocol (vitamin E), the paclitaxel particles residing inside the core, and the surfactants surrounding the emulsion particle. This emulsion system is still being researched and is in clinical trials [75].

Colloidal systems are yet another method to dissolve a previously insoluble drug compound in a delivery medium. Liposomes are an excellent example of the use of colloidal systems in drug formulation in recent times. These are explained in detail later on.

### 8.3 Stability

The next important property that must be considered in drug formulation is the compound's stability. Preformulation studies often will evaluate the chemical stability of the drug compound. They will also provide vital information on compound degradation and its breakdown products. Other factors that can be evaluated include the compound's response to various temperatures, pH, wavelengths of light, and even radiation. Once these factors are determined, appropriate delivery vehicles can be chosen more effectively. Lyophilization is one method that is commonly used in drug formulation today [76]. This method essentially is freeze-drying the compound so that it will remain stable for longer periods. Once the lyophilized compound is needed, it can be dissolved back into an appropriate solvent. Ultimately, the formulation of the drug should maintain the stability of the compound so that it can be easily stored, transported, and administered to patients in its most active form.

### 8.4 Liposomal Delivery

Liposomes are essentially spherical vesicles that consist of a phospholipid bilayer. This concept is based on basic cellular biology and the phospholipids bilayer that creates the cellular membrane. A phopholipid is an amphiphilic lipid that consists of a hydrophilic phosphate head and a hydrophobic lipid tail. Their amphiphilic nature allows them to self-assemble into spherical bilayers when introduced into an aqueous solution. These liposomes can be utilized to encapsulate various types of drug compounds. Lipophilic drugs can be captured within the lipophilic bilayer of the liposome. Water-soluble drugs can be encapsulated within the core of the liposome. Liposomal delivery can be used for improving solubility, changing biodistribution, allowing for controlled release, improving tissue penetration, overcoming multidrug resistance, and for facilitating targeted drug delivery [77].

As mentioned previously, liposomes are of significant interest in solubility due to their ability to deliver hydrophobic molecules by incorporating these molecules in the lipophilic bilayer. Paclitaxel is one poorly soluble agent that is currently being investigated for use with liposomes [72]. The liposomal paclitaxel showed comparable activity when compared with standard paclitaxel in mouse models. Additionally the in vivo half-life of liposomal paclitaxel was noted to be longer than standard paclitaxel. The drug distribution was enhanced as well. Because of these findings, liposomes continue to be a popular choice for the delivery of poorly water-soluble drugs.

Improved biodistribution to certain tissues has been another reason for the interest in liposomal preparations of drugs [78]. Liposomes favor distribution in regions that are lipophilic or that have improved vascular permeability. Tumor cells are noted to have the latter finding due to increased angiogenesis. Utilizing liposomes allows the systemic toxicities of the drug to be diminished due to less penetration in healthy organs. By improving biodistribution in this manner, liposomes allow for an improved therapeutic index. Additionally, the liposomal preparations can allow for locoregional therapy. This therapy works by injected the drug in certain region with the hope that the highest concentrations of the drug will remain in that area. Due to their lipophilic nature, liposomes will tend to remain in a specific tissue compartment longer than water-soluble compounds. A liposomal preparation of doxorubicin (Doxil) has been developed due to these concepts [79]. The liposomal formulation of doxorubicin was developed to reduce the number of systemic side effects sustained from standard administration of free doxorubicin. Using the liposomal delivery system allowed for better tumor absorption of the drug and changed the pharmacodistribution of the drug so that there were reduced concentrations in commonly damaged organs (e.g., cardiac tissue) [80].

As noted previously, liposomes can change the biodistribution of a drug. Along with this concept is the finding that liposomes can actually be used to overcome some biological barriers. By overcoming these barriers, liposomes are of special interest in helping to overcome cancers with multidrug resistance (MDR). The size of liposomes can be manipulated to make either small or large vesicles. By using smaller liposomes, one can deliver drugs into cells and potentially overcome the efflux mechanisms found in MDR cancer cells [77]. They can also be manipulated to help deliver the cells to specific compartments of the cell. This finding is quite intriguing and continues to be a significant area of research.

Controlled release continues to be an important concept in anticancer drug delivery. Liposomes are also great candidates for this technology. As mentioned above, liposomes can alter the biodistribution and in vivo half-life of a drug. This allows for controlled release of agents. Many factors come into play in controlled release, but it is important to know that due to their ability to be easily modified, liposomes continue to play a role in controlled release of drugs. An easy way to think of this is that in standard chemotherapy, the pharmacokinetics of the drug may allow for toxic concentrations of the drug to be reached immediately after infusion. Liposomes can delay this toxicity due to the entrapment of the drug in the liposomal system. Additionally, the drug will not be metabolized as fast when it is in the liposomal system. This can allow for a longer half-life after administration. In addition to these concepts, liposomes can also be formulated to be "sensitive" to specific environmental triggers. Changes in pH, temperature, and even the chemical environment in the target tissue can be "programmed" into the liposome to stimulate release [81]. These ideas in combination can allow for longer exposure to the drug after infusion and focused release in the target tissues. Utilizing these concepts can allow for higher concentrations of the drug to sometimes be used without increasing systemic side effects.

Targeted drug delivery is currently the area of most interest in anticancer drug development [82]. It is no surprise that liposomes have been an area of investigation regarding this field. Liposomes are essentially biological membranes that contain phospholipids and potentially other cellular components. In addition to phospholipids, the human cellular phospholipid bilayer contains various proteins and carbohydrate compounds. In human cells, these proteins and carbohydrates are used for cellular signaling and messaging. One can apply these findings to liposomes as well. Just as human cellular membranes can contain signaling proteins and carbohydrates, so can liposomes. A number of different ligands are under investigation for their use in liposomes. Antibodies, cytokines, hormones, growth factors, and even toxins can be incorporated into liposomal membranes. This allows for targeted delivery of the lipsomally delivered drug to specific cells. One interesting utilization of this concept is the development of immunoliposomes. An immunoliposome targeted against the *HER2/ErbB2/neu* oncogene (anti-HER2 immunoliposome) is currently being evaluated [83]. Researches have incorporated doxorubicin in this targeted liposome. Studies of both in vitro and in vitro use of this immunoliposome showed appropriate binding to cells overexpressing this mutation. Furthermore the liposomes were selectively internalized into these cells. These preclinical studies utilizing the anti-HER2 immunoliposome with encapsulated doxorubicin showed improvement of therapeutic efficacy compared to treatment with anti-HER2 antibodies alone or in combination with standard chemotherapy. These promising results have provoked further research and the doxorubicin immunoliposome is currently in clinical trials. Successful findings such as this further stimulate the interest in using liposomes for targeted delivery agents.

Although liposomes are of great clinical and intellectual interest, there are problems that must be evaluated and overcome before they are utilized more extensively. First of all, size is a factor in liposomal delivery [84]. Larger sized liposomes (larger than 200 nm) are usually very short lived due to rapid host response and destruction of the liposome when it reaches the mononuclear phagocytic system (MPS). Smaller sized liposomes (<70 nm) are shorter lived after infusion but have improved penetrance into more tissues due to their size. Intermediate sized liposomes (70–200 nm) tend to last longer after infusion due to their ability to avoid the MPS. Depending on the specific need for the liposomal system, an appropriate size must be determined and evaluated. Following this, storability is also an issue. Liposomes may have an insufficient chemical stability to maintain long-term shelf life. Various manipulations can be made to the liposome to improve its stability. Nevertheless, this remains an important pitfall to overcome. Another significant problem is the host immune response to liposomes. Liposomes are a biological component and can evoke immune responses. When signaling proteins or antibodies are added to the membrane, the chance for immunologic side effects is increased. The benefit versus the risk of adding these targeting mechanisms must be heavily weighed when developing this technology.

### 8.5 Polymeric Drug Delivery Systems

Liposomes continue to be a biologically derived technology that has been of interest for the delivery of anti-

cancer agents. Along with this idea comes the concept of utilizing polymers, both biologic and synthetic, to deliver anticancer agents. The utility of polymers is similar to that of liposomes in that the improvement of solubility, change in biodistribution, increased half-life, ability to overcome MDR, and improvement in therapeutic index can be achieved. Additionally, polymers can be easily manipulated to encorporate targeting moieties to allow for targeted drug delivery. Finally, polymers have the ability to be manipulated into many forms. This allows for the development of implants, microspheres, biogels, and even tablet formulations of polymer–drug conjugates.

In 1975, the idea of creating polymer–drug conjugates was first published by Ringsdorf [85]. His model hypothesized that the polymeric–drug conjugate systems could be used to improve pharmacokinetics of the drug attached to the polymer. Additionally, his hypothesis included the concept that a targeted delivery system could be developed using this system by including a homing moiety on the polymeric system. With the rise in interest in targeted delivery systems, this idea has been advanced further. As work has progressed utilizing polymeric–drug conjugates, studies have been showing that therapeutic efficacy can be improved by penetrance into target tissues and extended half-life of the compound [86]. Additionally, the number of side effects can be decreased. The stability of the drug compound can be improved utilizing polymeric–drug conjugate systems as well. Of course, these polymeric systems also allow for the addition of targeting moieties to the polymeric backbone. It is no surprise that a number of these agents have been developed encorporating a number of chemotherapeutic agents [87].

Perhaps the best example of the polymer–drug conjugate systems is the synthetic polymer–drug conjugate poly(L-glutamic acid) with paclitaxel (PG-TXL, CT-2103; Xyotax) [88]. PG-TXL was initially created to overcome the poor solubility of paclitaxel and the hypersensitivity reaction of the standard administration of paclitaxel in Cremaphor EL. The PG-TXL polymer–drug conjugate involves the conjugation of paclitaxel to the synthetic polyamino acid, poly(L-glutamic acid) through the 2′-hydroxyl group via an ester linkage. This conjugation increases the water solubility of paclitaxel significantly. In preclinical studies this polymer–drug conjugate displayed improved antitumor activity and decreased side effects compared to standard paclitaxel delivered in Cremaphor EL [89]. PG-TXL has been evaluated in mouse models of human breast cacners, ovarian cancers, and lung cancers and has shown significant activity. Biodistribution was also noted to be different with PG-TXL with up to five times greater tumor exposure when compared to Cremophor-EL-delivered paclitaxel. The amount of time that the tumor was exposed to the drug was increased almost six times more than the standard preparation when the PG-TXL compound was injected into mouse tumors. Overall, the improved therapeutic index of PG-TXL when compared to the standard preparation was determined to be due to enhanced permeability and retention (EPR).

Furthermore, PG-TXL is of special interest due to its use in several phase I, II, and III clinical trials. Phase I and II trials in a broad range of tumor types including gastric, esophageal, breast, and ovarian cancer showed improved side effect profiles in regards to alopecia, nausea, vomiting, and especially hypersensitivity reactions [88]. The STELLAR 2, 3, and 4 phase III clinical trials compared efficacy of PG-TXL compared to several standard chemotherapy regimens for non-small-cell lung cancer (NSCLC) [90]. In these studies, the PG-TXL showed no statistical improvement in overall survival when compared to the standard treatments. Currently, there is a trial underway that is comparing the use of PG-TXL in combination with carboplatin and comparing this to standard paclitaxel and carboplatin.

Although PG-TXL has been the most successful polymer–drug conjugate to date, there are a number of other potential candidates. Many of these conjugates are in preclinical studies, but a number have made it to clinical trials. The polymers *N*-(2-hydroxypropyl) methacrylamide (HPMA), polyelthyelene glycol (PEG), and cyclodextrin-based polymers are currently being used to deliver a number of standard chemotherapy drugs in clinical trials. Some polymer–drug conjugates and references to their clinical studies are outlined in Table 16.

Polymer–drug conjugates continue to be very interesting candidates for improving anticancer drug delivery. Their ability to be modified to target specific tumor types will solidify their acceptance into the anticancer drug delivery field. Furthermore, their uncanny ability to be formulated into various release systems will allow more opportunities to be able to utilize these

**TABLE 16 Polymer–Drug Conjugates in Clinical Trials**

| Polymer–Drug Conjugate |
|---|

| PEG–SN38 |
| Cyclodextrin-based polymer–camptothecin (CPT) |

drugs beyond the standard intravenous approach. Future directions that will continue to be explored will be the use of conjugates that can be used in combination with radiotherapy and ultrasound for controlled-release, polymer–prodrug conjugates in conjunction with polymer-directed enzymes, and the use of polymer–multidrug conjugates to deliver combination chemotherapies.

## 8.6 Prodrugs

Another aspect of drug delivery research has been focusing on the development of prodrugs. Prodrugs are essentially an inactive or less active form of a drug compound. The idea behind prodrugs is that they will become the active drug under the right circumstances. By being inactive or less active initially, the pharmacokinetics and biologic activity can be altered. The thought processes that led to the development of prodrugs focused on changing biodistribution, solubility, absorption, metabolism, and excretion. Specifically, many prodrugs were created so that a drug could be administered via an oral route versus the traditional intravenous approach.

Prodrugs typically require one to many metabolic steps to become active. This can involve spontaneous changes or, more commonly, enzyme-mediated changes. Due to this, the prodrug must remain similar in structure to the final drug compound. In order to reach the final drug's structure, the prodrug must contain chemical bonds that can be cleaved or changed to eventually change the prodrug into the drug. These reactions are typically done by enzymes present in the host but can occur spontaneously. Once the drug is converted, it must be able to be absorbed by the target cells. Additionally, it is ideal if the prodrug is not excreted prior to conversion to the drug. Furthermore, one must be sure that during the reactions to make the prodrug into the drug compound that minimal or no toxic metabolites are created as side products of the reactions.

There are two classifications of prodrugs, types I and II [91]. Type I prodrugs are converted to the final active drug intracellularly. Type II prodrugs are converted extracellularly. These classifications are further categorized by the subtypes A and B. The subtypes IA and IB determine whether or not the prodrug is converted at the site of therapeutic action. Type IA prodrugs are converted at the therapeutic target (tumor cells), while type IB prodrugs are converted in the metabolic tissues (liver, lung, kidney, etc.). A type IA and IB category can both apply to some prodrugs when the site of the therapeutic target and conversion is the same. Because type II drugs are converted extracellularly, the subtypes A and B have different meanings. Type IIA prodrugs are typically converted when they are in the gastrointestinal (GI) tract after they have been taken orally. Type IIB prodrugs are absorbed through the GI tract and converted into the drug when they reach the systemic circulation.

Because tumor cells have altered metabolic activities when compared to normal, healthy cells, the use of prodrugs has become of great interest. As the fields of genomics, proteomics, data mining, and HTS have evolved, we are seeing the potential benefits of prodrugs. Our knowledge of the intracellular enzymatic process has grown exponentially. These intracellular processes can be exploited by the use of appropriately created prodrugs. By creating a prodrug that will be selectively activated by tumor cells, tumor-targeted drug delivery can be achieved.

One successful example of a prodrug is the agent capecitabine. Capecitabine is a prodrug of 5-fluorouracil (5-FU) [92]. It is currently registered for use as a monotherapy in colorectal cancers and taxane- and anthracycline-resistant breast cancers. It has also been approved for use in combination with docetaxel in locally advanced or metastatic breast cancer. Capecitabine is a type IA prodrug. The drug is an oral formulation that can be easily administered in an outpatient setting. After oral administration, capecitabine is taken up in the GI tract and converted into two major metabolites, 5′-deoxyfluorocytidine (5′-DFCR) and then 5′-deoxy-5-fluorouridine (5′-DFUR). The 5′-DFCR is created in the liver by carboxylesterase enzymes. The 5′-DFUR is created from the 5′-DFCR by cytidine deaminase, which is present in the liver and tumor tissue. Once the 5′-DFUR has been created, it is then converted into 5-FU intracellularly by thymidine phosphorylase. Thymidine phosphorylase is often overexpressed in tumor tissue. There is a small amount of the prodrug that is converted to 5-FU directly after absorption. However, the amount of 5-FU in the systemic circulation is minimal and can be decreased by concomitant food intake with drug administration.

Capecitabine has been quite successful due to its tumor selectivity and reduced systemic side effects when compared to standard 5-FU. It has begun to replace 5-FU in many chemotherapy regimens and may someday replace it entirely. Due to its success, more prodrugs are being developed. With expanding knowledge of cancer genomics and proteomics in combination with data mining, HTS, and bioinformatics, we can expect to see many more prodrugs like capecitabine coming through the research pipeline.

## 8.7 Nanoparticles

Nanotechnology and more specifically nanomedicine have been important areas of medical research in current years. In regards to anticancer drug research

perhaps the most important area has been the area of nanoparticles. There are a number of synthetic and biologic nanoparticles available today. A nanoparticle is typically defined as a particle with its dimensions between 1 and 100 nm in any dimension [93]. This definition has changed over the years and the dimensions have been expanded somewhat. Examples of nanoparticle systems being investigated currently include liposomes, dendrimers, micelles, polymer–drug conjugates, silica nanoparticles, quantum dots, and even cellular proteins. The utility of nanoparticles is similar to other areas of drug delivery and includes improved therapeutic index, decreased systemic side effects, altered biodistribution, and the ability to be modified for targeted drug delivery. Perhaps the best way to show the utility of nanoparticles is to give an example.

Abraxane is a novel Cremophor-EL-free, albumin-bound, 130-nm form of the chemotherapeutic agent paclitaxel [94]. This agent is created by the high-pressure homogenization of paclitaxel in the presence of human albumin. It results in a nanoparticle colloidal suspension with paclitaxel–albumin nanoparticles ranging from 130 to 150 nm in mean diameter. Due to their size and water solubility, the albumin-based nanoparticles are easily soluble in an aqueous solution and can be administered intravenously without significant Cremaphor-EL-related side effects. In addition to this, the nanomolecules exploit the gp60 receptor. The gp60 receptors are specific for albumin as a ligand [95]. They allow for the intracellular transport of albumin. Because these receptors are commonly found in endothelial cell walls, they are often present in larger concentrations in the area of a tumor. This is due to increased angiogenesis to feed tumor growth. As a result, the albumin-bound paclitaxel has greater intratumor concentrations than an equivalent dose of Cremaphor-EL-delivered paclitaxel. Due to this finding, Abraxane requires less volume and administration time than standard paclitaxel. Additionally, the lack of Cremaphor EL eliminates the need for anaphylaxis prevention with steroid pretreatment.

Abraxane displayed the utility of nanoparticles in clinical oncology when it became approved by the U.S. Food and Drug Administration (FDA) in 2005 for the treatment of relapsed or refractory breast cancer. Its success has stimulated further work in the area of nanoparticle anticancer drug delivery systems. Albumin-bound formulations of docetaxel and rapamycin are currently being researched. Further work is currently being done with a variety of chemotherapeutics using a number of nanoparticles.

### 8.8 Conclusions

As if the discovery of the drug compounds was not vast enough, drug delivery remains a vital part of developing a potential anticancer drug. Drug formulation is an initial hurdle that must be overcome to ensure that the drug will maintain its integrity, activity, and effectiveness. When drug formulation proves to be difficult, other drug delivery options must be pursued. Advances such as liposomal delivery, polymer–drug conjugates, prodrugs, and nanoparticles are providing new techniques to facilitate drug delivery. In addition to facilitation of drug delivery, these options are giving researchers the ability to adapt tumor-specific targeting mechanisms to cytotoxic agents. The field of drug delivery will likely thrive along with the fields of drug discovery in the years to come.

## 9 IN VITRO CELL LINES

As with many other fields of drug discovery, cancer drug discovery begins in the laboratory. Before a potential chemotherapeutic agent is even considered for use in animal research, it must first be tested in vitro. By studying the effects of potential anticancer agents in vitro, researchers can determine if further work should be done in in vivo studies.

Cancer cell lines provide the first step in the evaluation of potential anticancer agents. This process is essentially a screening procedure in which a potential drug is put through several different steps to determine if it is worthy of further development. A good example of this type of screening can be explained by the National Cancer Institutes (NCI) Development Therapeutic Program [96]. In this screen, a potential cancer agent is first put through a prescreen in which it is exposed at a fixed concentration to three different cancer cell lines for a 48-h period. If there is any activity in any of these prescreen cell lines, the compound is then moved on to be tested in the more diverse NCI 60 cell lines. These lines consist of lung, colon, melanoma, prostate, ovarian, breast, and kidney cancer cell lines. The composition and methods involved in the NCI 60 cell lines is explained later. Depending on the distribution of activity in each tumor type, the potential drug may be tested in further related cell lines or it may progress on to in vivo experimentation.

In both in vitro and in vivo testing the main outcome being evaluated is drug activity on the tumor cells. Drug activity is assessed in in vitro studies by evaluating growth inhibition or cytotoxicity. Assessing for this involves the use of a quantified technique in which to exactly measure and compare the amount of inhibition or cytotoxicity. Colorimetric assays have grown to become the standard for these measurements.

There are a multitude of colorimetric assays currently available. They all utilize the same basic idea however. With the advent of fiber-optic, multiwell

sensors integrated with computer interfaces, these assays can be rather efficient and precise. This coupled with the popularization of multiwell microtiter plates allows for rapid analysis of multiple drug activity assays at once. The basic premise of colorimetric assays starts with culturing cells in multiwell microtiter plates. Now 96-well microtiter plates are often used for culturing. In each well there will be a specified number of cells that are allowed to be grown. This way each plate has the same or very close to the same number of cells present to be tested. Once the cells are allowed to grow to the specified number, various concentrations of the anticancer agent is applied to each microtiter plate. One row or group of cell cultures is kept as a control and is not exposed to the drug. After a specified time period has elapsed, the cell cultures are ready to be evaluated for drug activity. At this point the colorimetric assay is utilized. Typically this works by adding a chemical or chemicals to each well that is absorbed by the remaining, living cells. This chemical will then cause the living cells to exhibit a certain color. The wells containing the cells are then placed into a computer interfaced, fiber-optic spectrophotometer, which will send a specified wavelength of light through the wells. The sensor then evaluates how much of the light is absorbed in each well. This data is stored in the computer and can be extrapolated to determine the percentage of living cells in each well. This data can thus show the effects of varying concentrations of the potential anticancer agent on specific cancer cell lines.

An excellent example of this method can be shown by MTT assays currently used in our lab. MTT [3-(4,5 dimethylthiazol-2-Yl)-2,5-diphenyltetrazolium bromide] assays work through the intracellular reduction of tetrazolium salts to purple-colored formazans [97]. This reaction occurs in living cells in culture and allows for easy spectrophotometer analysis at a wavelength of 500–600 nm. MTT assays are quite beneficial as they can be easily automated and are quite precise. An example of the utility of these assays can be shown by its use in the evaluation of MT-103, an experimental compound derived from a topological computer model, currently being evaluated in our lab. Using the MTT assay, we evaluated varying concentrations of this drug on H226 lung cancer cell lines over a 48-h period. The type of data obtained from the assay can be seen in Figure 1.

As indicated from the example above, one can compare the activity with varying concentrations of the drug. This example indicates that as the concentration of the drug was increased, more activity was noted. Most often a trend of more inhibition or cytotoxicity can be noted with increasing concentration of the drug. However, in some cell lines, there may be no discernable activity of the agent. Other factors such as drug solubility, bacterial or viral infection of the cell lines, cell mutation, faulty culture media, inappropriate measurement of drug, and stability of the colormetric agent can play a role in causing error in colormetric assays. Regardless of this, they remain standard in evaluating drug activity in in vitro studies.

**Figure 1** H226 (5000 cells/well) + HT103 in DMSO alone after 24 h.

As mentioned previously, the first step in anticancer drug testing involves the use of in vitro testing. This utilizes various cancer cell lines. The current trend is to utilize modern technologies to allow for rapid and standardized methods to run and evaluate these experiments. Colormetric assays allow for this rapid and standardized approach. The NCI 60 cancer cell lines are the best example of this and warrant further discussion.

## 10 NCI 60 CANCER CELL LINES

Up until the late 1980s, drug discovery was mostly based on evaluating drug activity on transplantable murine tumor models. This had been proving useful for finding drugs to treat leukemia. However, the more common human solid tumors, breast, lung, colon, and prostate were proving difficult targets for anticancer agents. Due to this problem, the need for a standardized and effective method to test the activity of drugs on these cell types was present. Specifically, interest in the treatment of lung cancer initiated the development of human lung cancer cell lines that were expanded to include other tumor types, which now compose the present-day NCI 60 cell line [96].

The NCI 60 cell line has proven to be a useful research tool in the past and is currently still vital today. As previously mentioned, the cell line was created as a means to find more agents for the treatment of human solid malig-

**Figure 2** Example evaluation of compound activity (here MT103) against NCI 60 cell lines.

nancies. It initially found its roots in lung cancer cell lines. Once these lines were created, the need for control groups was understood. Fibroblasts are normal human cells that are resistant to almost all types of chemotherapeutic agents. On the other hand renal epithelial cells are overly sensitive to most anticancer agents. After these controls were added, more human solid tumor types were added. Finally the NCI 60 cell line consisted of nine separate groups of human solid tumors: breast, lung, colon, central nervous system (CNS), prostate, renal, melanoma, ovarian, and leukemia.

The basic principle of the cell line was to have a standardized and efficient way to evaluate the growth inhibitory or anticancer effects of different compounds on the cell lines. These cell lines have also proven to be useful in evaluating drug resistance patterns and molecular activity of drugs. The NCI 60 cell line has seen a great deal of change since its inception, but the basic principle of evaluating potential drug activity remains paramount.

Various different cancer cell lines have commonly been used in cancer research. When the NCI 60 cell line was initially developed, there were more than 1000 different cell lines investigated. This large number of cell lines, of course, defeated the purpose of the screen, so the most promising lines were chosen. Favorable properties of the cell lines chosen included acceptable growth rates, adaptability, resistance to infection, and variable drug sensitivity. Ultimately 60 different cell lines were chosen.

It is important to understand how the NCI 60 cell lines are used. The model is an in vitro screening system. The NCI 60 cell lines are plated in multiwell tissue culture dishes. The cells are allowed to grow to reach a specified number of cells per well. When this number has been reached, the experimental drug is added at five different doses for 48 h. Once the 48 h has passed, a colorimetric assay is used to determine the growth inhibitory or cytotoxic effects of the agent. An example of a reading from an NCI 60 cell line is shown in Figure 2.

The drug may show activity in one specific cell line over another, which can give details about its possible mechanism of action. It may also show broad activity over a number of different types of cell lines. Regardless of this, if the agent shows promising activity in any cancer cell lines, it will likely be moved on for further testing. This further testing may be further more detailed in in vitro studies to determine the exact mechanism of action of the drug or it may jump to the next stage, in vivo testing. Approximately 2500 compounds a year are tested using the NCI 60 cell lines. Of these compounds, about 2% will move on to in vivo studies [96]. Due to the large number of anticancer agents being evaluated every year, it is important to have solid screening tools. The NCI 60 cancer cell lines remain an invaluable screening tool.

## 11 IN VIVO STUDIES

After a compound is shown to have activity in an in vitro setting, testing in an in vivo setting is desired. Anticancer drugs cannot move directly into human research until appropriate information is obtained regarding toxicity, dosage, and administration. In vivo studies provide the arena to find this data. These studies can be done using a variety of animal subjects; however, the mouse is most commonly used. Due to their size, durability, and easiness to handle, mice have been used in in vivo studies for years.

### 11.1 Mouse Models

Mouse models can be developed through a variety of methods. Mouse studies initially were done using mice with spontaneous arising tumors or by chemically inducing a malignancy. Fortunately, the ability to create immunodeficient, nude mice has come to fruition [98]. The use of these mice allows the ability to transplant tumors to normal, healthy mice. These mouse tumor models are either murine allograft models or human xenograft models. Murine allograft models are essentially tumor models that involve the transplantation of a murine or mouse tumor to a nude, immunodeficient mouse. Human xenograft models involve transplanting human tumor cells to a nude, immunodeficient mouse.

These mouse tumor models typically involve the transplantation of a predetermined number of tumor cells to a site other than the primary site of the malignancy (i.e., the flank). Sometimes the cells will be implanted orthotopically at the site of the primary malignancy. However, this is not a commonly used approach due to difficulties in implantation and tumor size measurement. Because the tumor cells are implanted in an immunodeficient environment, they are able to proliferate without any host response. The size of the tumor is monitored closely until it reaches a predetermined size. Once the tumor reaches the necessary size, the mice are divided into control and treatment groups. The treatment group is given the drug or combination of drugs as determined by the study design. The control group is given a placebo, usually normal saline. Tumor growth is monitored closely throughout the study. Additionally, the mice are monitored for any adverse effects. The adverse effects seen in mice give important information for later studies. They can often provide some preliminary information on drug toxicity. Throughout the study, the tumor response to therapy and placebo is recorded. At the end of the study, the effect of treatment is compared to the effects of placebo. Another parameter that is evaluated at the end of the study is animal survival. This is often a measure of how toxic the drug is in an in vivo setting. Ultimately, the goals are to see that the drug had significant activity compared to the control in vivo and does not display significant toxicity at the utilized doses.

Mouse models also require a great deal of supervision. In the United States there are a number of advisory and regulatory committees that monitor the treatment of animals used in studies. These groups are present to ensure that the animals are not inappropriately harmed or mistreated in any way. They typically review studies before they can be initiated and will monitor the research process to ensure that appropriate care is given to the test animals.

Mouse models provide an additional step to evaluate the efficacy of an anticancer agent on various types of cancer. They also allow researchers to see how a drug will work in an environment with active organ systems and metabolism. Additionally, in vivo models will provide preliminary toxicity data. Unfortunately, these models are not perfect. Transplanted human tumors do not grow and proliferate as they do in their primary site in humans. Differences in anatomy and physiology at these sites are part of the reason. Interestingly, orthotopic human tumor models do not show similar growth either [99]. Due to this, it is important for promising agents to move on to clinical studies in humans before being finally approved for use. Despite this, mouse and other animal models will continue to play an integral role in the preclinical development of anticancer agents.

## 12 CLINICAL TRIALS

Clinical trials are major hurdles for a potential drug to overcome before it can be used clinically. These studies are not designed to make it difficult for an experimental agent to become an approved drug. They are designed to make sure that the drug is safe, effective, and appropriate for its intended use. Because they use human subjects, clinical trials are very heavily regulated. Institutional review boards (IRBs) are integral in the control of these studies. These committees work to approve, monitor, and review clinical trials to ensure that the subjects are not harmed or abused. Clinical trials are vital in anticancer research. They involve three major steps and are divided into phase I, phase II, and phase III clinical trials.

### 12.1 Phase I Clinical Trials

Anticancer agents go through a rigorous preclinical research process. If they show promising activity in in vitro and in vivo preclinical studies, they will often

move on to clinical studies. The first step is the phase I clinical trial.

Phase I clinical trials are created with the goal of finding the appropriate dosing of a drug or combinations of drugs [100]. They also help to evaluate initial pharmacologic and pharmacokinetic data. These trials are designed as dose escalation studies. In cancer clinical trials, only patient's with a known malignancy are allowed in the study. These patient's typically have end-stage disease and lack further treatment options. The major goal of these studies is to determine the maximum tolerated dose (MTD). The MTD is the maximum dose that can be achieved while still having an acceptable level of dose-limiting toxicity (DLT). When evaluating the MTD, one must account for patients that may have organ damage from their disease. Some drugs are metabolized and excreted via certain organs. For example, patients with kidney or liver damage from their disease may notice more toxicity from certain drugs. This must be accounted for prior to the study. These patients are often excluded from these studies. Otherwise, a number of different patients with different tumor types will be included in these studies.

The basis of designing these studies is to determine the correct dose escalation of the drug. By escalating the dose too rapidly, patients can be exposed to excessive toxicities. Escalating the dose too slowly can expose patients to ineffective levels of the drug and deny them adequate therapy for their cancer. The first step in designing these trials is to decide upon an appropriate starting dose. This dose should be relatively safe overall but must not be too low as to make it ineffective. The starting dose is typically extrapolated from doses used in previous animal studies. Toxicity is usually thought to be a function of body weight. This is relatively constant throughout species. The starting dose can be determined using the concept of allometric scaling. Allometric scaling allows for the comparison of two different species of different sizes. This concept has been used to predict the rough equivalent MTD in humans when compared to mice. The murine equivalent $LD_{10}$ ($MELD_{10}$) is the dose associated with 10% lethality in mice. This dose is approximately the MTD in humans. When a second species is needed to determine the MTD, the canine is commonly used. In this situation the lethal dose ($LD_{10}$) is used rather than the $MELD_{10}$. The typical starting dose for phase I trials is usually one-tenth the estimated MTD based on the $MELD_{10}$ or one-third the $LD_{10}$ [101].

The difference that sets phase I clinical trials apart from one another is the rate of dose escalation. There are a number of different models for dose escalation, but they can be easily categorized as single ascending dose (SAD) studies and multiple ascending dose (MAD) studies. The SAD studies involve starting at a single starting dose. The patients are closely monitored after getting the dose for side effects. Pharmacokinetic data is also evaluated after the dose. If there are no adverse effects and there is adequate pharmacokinetic data, the dose will then be escalated in a new group of patients. This will be continued until the MTD is reached. MAD studies involve giving multiple doses of the drug. Patients are given multiple low doses of the drug. Pharmacokinetic data is taken through these doses at predetermined points. These types of studies are useful for understanding pharmacokinetics and pharmacodynamics.

### 12.2 Phase II Clinical Trials

Once the MTD has been determined from phase I studies, the next step is to evaluate its activity. Phase II trials are the next evaluation process. These studies usually have larger patient groups than phase I trials. Phase II trials are designed to evaluate the efficacy of the drug and to further evaluate its safety [102]. Tumor response to the drug is usually the major clinical endpoint in these studies. Ultimately, these studies are used to discern between potentially active agents and agents with minimal or undesired activity. Drugs are essentially "weeded out" during these studies. Successful drugs may then be further evaluated in follow-up phase II studies or they may move on to phase III studies.

### 12.3 Phase III Clinical Trials

The final step before being an approved agent is the phase III clinical trial. These studies are the largest and most time-consuming studies. They are often randomized, controlled, multicenter trials [102]. These studies are also usually very expensive and difficult to run. They require a great deal of participation from both the patients and the researchers. These studies are utilized to determine just how effective the drug is compared to the gold standard. Along with testing the drug's effectiveness, phase III trials provide a larger group to investigate adverse effects. Less common adverse effects are often picked up during phase III trials due to the large number of patients.

Phase III studies will often test a drug compared to a control. In clinical trials in general, this control can either be a placebo or the standard therapy used in practice. In cancer clinical trials, it is unethical to deny one group a potentially beneficial therapy, so the use of placebo is unethical. For this reason, another drug, often the standard therapy, will be used. If the test drug shows adequate efficacy compared with the control and has tolerable side effects, it will often move on to the drug approval phase. The drug approval phase involves the

submission of a detailed document explaining the methods and results of all research utilizing the drug. Additionally, information must be given regarding the mechanism of action, proper formulation, dosing, and correct administration. If the drug shows significant efficacy based on well-designed and well-controlled studies, a reasonable side effect profile, and a feasible route of administration, it will likely be approved.

The path to drug approval is a very long process, especially in anticancer drug research. Preclinical studies can take around 6–8 years before the drug is ready to enter clinical studies. Clinical studies can take a similar amount of time before adequate data is obtained. For this reason, there are a number of policies and procedures that have been developed to ensure that a drug can be available to the market as rapidly as possible. These steps include: the Fast Track Program and Rolling NDA Submission, the Accelerated Approval, Special Protocol Assessment, and Priority Review [102]. These procedures are typically reserved for agents that show significant benefit over standard therapy in initial studies. By using these pathways, a drug can move through clinical studies more rapidly. To better understand each of these procedures, please see their corresponding references.

The clinical trial process is lengthy and information intensive. These studies provide the information needed to get a drug to move on to clinical practice. Vital information pertaining to efficacy, adverse effects, dosing, and improvement of survival can be obtained from clinical studies. It is important that these studies continue to be heavily regulated and monitored to ensure that patient's are getting the best care possible and not being harmed. Clinical trials will continue to play a pivotal role in anticancer drug discovery, therefore understanding the processes and procedures involved is important for all researchers.

## 3 FUTURE DIRECTIONS

Anticancer drug research has a vast array of technologies at its disposal. Many promising agents have been found over a relatively short period of time. By utilizing new technologies, we are able to realize many different ways to treat cancer. The protein kinase inhibitors are perhaps the newest class of drugs that illustrate our enhanced understanding of cancer biology. Fortunately, this is not the end of the road for anticancer research. Several new avenues are just beginning to be explored.

Antisense drugs are one class of compounds that are being explored. By targeting specific RNA sequences with designed complementary oligonucleotides, one can target specific genetic expressions in cancer cells [3]. This "gene therapy" can be used to inhibit production of abnormal proteins by the erroneous RNA in cancer cells. Additionally, gene therapies may be able to be used to target cancer cells and create proteins that induce apoptosis. This is an exciting area of research that will continue to be explored as our knowledge of genetics continues to expand.

In addition to this we will continue to see more sophisticated methods of drug delivery. The advancement of nanomedicine is perhaps one of the reasons why drug delivery is becoming such an interesting area. For instance, the development of protein cages, based on the idea of viral capsids, are currently being evaluated for their use in drug delivery. These delivery mechanisms are similar to liposomal delivery but may have the ability to be more easily manipulated or altered for targeted delivery. Concepts such as this will continue to stimulate further research in the area of drug delivery.

## 14 CONCLUSION

The field of anticancer drug research is vast. As our understanding of cancer biology grows, so will our ability to create new cancer drugs. By keeping the interests of the patient in mind, we must remember that the most effective agents are those that have maximal efficacy in addition to limited side effects. We may never be able to eradicate cancer, but we can hope to improve the quality of life of those who have it. As long as cancer remains a major cause of morbidity and mortality, anticancer drug research will continue to grow.

# TYROSINE KINASE INHIBITORS IN CHRONIC MYELOID LEUKEMIA

Muhammad Mansoor Alam and Moshe Talpaz
*University of Michigan School of Medicine, Ann Arbor, Michigan*

## 1 IMATINIB

### 1.1 Introduction

The BCR-ABL protein tyrosine kinase is the product of a chimeric gene produced by the Philadephia (Ph) chromosome. Initially identified in 1960, the Ph chromosome results from a reciprocal translocation between the long arms of chromosomes 9 and 22. Chronic myeloid leukemia (CML) is a myeloproliferaive disorder that results from this acquired mutation affecting hemapoietic stem cells. Imatinib, also known as Gleevac, developed by Novartis, is a specific inhibitor of BCR-ABL tyrosine kinase. If untreated CML inevitably progresses to more aggressive accelerated and blast phases. Once in blast phase the median survival of patients is less than 6 months. Imatinib has substantial activity in the chronic phase, as well as significant activity in the accelerated phase and the blast crises phase of CML [1, 2].

### 1.2 Mechanism of Action and Development

There is a family of enzymes called protein tyrosine kinases that bind adenosine triphosphate (ATP) and catalyse the transfer of the γ-phosphate to the hydroxyl group of a tyrosine residue on a protein. In a signal transduction cascade these phosphorylated sites can then serve as binding sites for phosphorylation of other substrates. The kinases themselves are usually activated either by interaction of a ligand with a receptor located within the extracellular domain of the kinase or, alternatively, as part of an intracellular signaling pathway. The human genome encodes upto 800 serine/threonine and tyrosine protein kinases, all of which bind ATP in a highly conserved fashion within their catalytic domains. Molecules collectively referred to as kinase inhibitors that are currently available possess an inhibitory profile whereby they inhibit the target kinase with relative selectivity toward other often closely related kinases to give an acceptable side effect profile [3].

In vitro and animal studies have established that BCR-ABL alone is sufficient to cause CML, and mutational analysis has established that tyrosine kinase activity of the protein is required for its oncogenic activity [4]. The ABL gene encodes the tightly regulated nonreceptor protein tyrosine kinase cytosolic ABL (cAbl), which plays a fundamental role in regulating cell proliferation, adherence, and apoptosis [5]. In contrast, the BCR-ABL fusion gene encodes a constitutively activated kinase. This transformation results in hemopoeitic stem cells to exhibit deregulated clonal proliferation, reduced adherence to bone marrow stroma, and reduced apoptotic response to disruption in cellular genomic integrity. As a result immature cells of the myeloid lineage are released into the blood in various stages of maturation as well as populate the reticuloendothelial system organs such as the liver and the spleen [6, 7].

This has rendered BCR-ABL an attractive target for drug intervention in CML. Unlike membrane-bound receptor tyrosine kinases, BCR-ABL is a cytoplasmic kinase. It is constitutively active and does not depend

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

on ligand binding and subsequent receptor dimerization or activation. Because of this reason BCR-ABL activity cannot be modulated by means of receptor-based inhibitions. The most obvious approach in this situation would be based on an ATP-competitive inhibitor of the BCR-ABL, which will result in blocking the kinase activity, as a result stopping this enzyme cascade [8, 9].

After the identification of BCR-ABL as a suitable target, Novartis (based in Basel, Switzerland) screened its large and diverse compound archive, which led to the identification of a pyrimidine structure as an attractive lead molecule for activity against cABL. Further development of the molecule occurred after structure–activity studies led to *N*-acyl and *N*-aroyl amide derivatives. Subsequently, methyl substituent ortho to pyrimidinylamino group controlled activity against other kinases and at the same time enhanced potency against cABL. The resulting molecules were noted to be highly insoluble. This was overcome by introducing suitably placed hydrophilic moieties. This resulted in the development of imatinib.

Imatinib binds only to the inactive conformation of BCR-ABL and is a potent, competitive inhibitor of cytosolic BCR-ABL. Imatinib also inhibits cKit and platelet-derived growth factor (PDGFR)-β, but is devoid of activity against other kinases including the Src family of kinases. The chemical designation of imatinib mesylate is 4-[(4-methyl-1-piperazinyl)methyl]-*N*-[4-methyl-3-[[4-(3-pyridinyl)-2-pyrimidinyl]amino]-phenyl]benzamide methanesulfonate. (See Fig. 1.)

### 1.3 Pharmacokinetics

Imatinib is well absorbed orally. It is available in a formulation as a methane sulfonate salt, which has good water solubility. It has an excellent pharmacokinetic profile. Maximum plasma concentration is achieved within 2–4 h after ingestion. Imatinib is 95% bound to plasma proteins, mainly albumin and α-1-acid glycoprotein with a mean bioavailability of 98%. A 400-mg/day dose of imatinib achieves fairly predictable plasma concentrations. Peak levels are noted to be 2.6 ± 0.8 mcg/mL and trough levels 1.2 ± mcg/mL, which easily exceed 0.5 mcg/mL concentration that is needed for tyrosine kinase inhibition in vitro [11]. (See Fig. 2.)

Imatinib is metabolized in the liver mainly by the CYP3A4 isoenzyme of the cytochrome P450 system. The major circulating active metabolite is the N-demethylated piperazine derivative, formed predominantly by CYP3A4. This active metabolite demonstrates in vitro potency similar to the parent drug and has a plasma area under the curve that is approximately 15% that of the parent drug. The mean elimination half-lives of imatinib and its active metabolite are 18 and 40 h, respectively. Elimination is predominantly through

**Figure 2** Mechanism of action of imatinib. By occupying the ATP-binding pocket of the ABL kinase domain, imatinib prevents substrate phosphorylation and downstream activation of signals, thus inhibiting the leukemogenic effects of BCR-ABL on cells in chronic myelogenous leukemia. ADP = adenosine diphosphate; ATP = adenosine triphosphate; P = phosphate group [10].

**Figure 1** Chemical structures of imatinib, nilotinib, dasatinib, and bosutinib.

the gastrointestinal tract in feces [11]. Imatinib or its metabolites are not significantly excreted through the kidneys. There is a potential for drug-to-drug interactions, especially with either inducers or inhibitors of the CYP3A4 isoenzyme. Therefore, drugs that induce imatinib metabolism may decrease the clinical activity of imatinib, while drugs that inhibit imatinib metabolism may lead to toxic side effects [11].

### 1.4 Clinical Efficacy

Imatinib is currently the standard first-line therapy for all patients with CML. In a landmark phase 1 study 98% of subjects in the chronic phase of CML that were treated with imatinib demonstrated a complete hematologic response, with 54% showing a cytogenetic response [4]. Response rate in myeloid blast crises of CML was 55%, and the rate of complete remission was 11%. Response rate has been noted to be 70% and complete remission 20% in patients with lymphoid blast crises or Ph + chromosome ALL [1]. Subsequent phase II studies confirmed these findings. Based on remarkable remission rates with imatinib in patients that were previously treated with interferon-α, the U.S. Food and Drug Administration (FDA) approved the drug for patients with CML [12–15]. There has been a dramatic impact of imatinib on survival in patient with CML. In a long-term study with 5 years follow-up of patients, with continuous treatment of chronic-phase CML with imatinib as initial therapy was found to induce durable responses in a high proportion of patients. With a median follow-up of 60 months, Kaplan–Meier estimates of cumulative best rate of complete cytogenetic response was 69% by 12 months and 87% by 60 months. Estimated overall survival was noted to be 89% at 60 months [16]. (See Fig. 3.)

**Figure 3** Kaplan–Meier estimates of the cumulative best response to initial imatinib therapy [16].

When a person is on imatinib, the annual risk of disease progression decreases with time. The overall risk of progression is dependent on degree of response regardless of when it is achieved. At 1 year the annual rate of progression with partial cytogenetic response is 1.4%, with complete cytogenetic response it is 0.6%, and with major molecular response it is 0%. Patients with major molecular response have been noted to have 100% survival at 2 years [17]. In case of annual event rates in patients after achievement of complete cytogenetic response on imatinib as the first-line treatment, 2.1% progressed to accelerated phase or blast crises in the first year after achievement of complete cytogenetic response, whereas in the fourth year none of the patients progressed to either accelerated phase or blast crises phase of CML. Late responses to imatinib occur and responses are durable.

### 1.5 Dosage

Imatinib is available in 400-mg tablets. There is no weight adjustment required, and the starting dose of imatinib mesylate in the chronic phase of CML is 400 mg per day. There is some greater benefit reported with doses greater than or equal to 600 mg/day during different stages of CML. This approach has been tried versus starting patients on newer medications [18]. In a phase II study patients who were previously treated with 400 mg/day of imatinib were given doses of 600 mg/day during accelerated phase of CML. Doses of 600 mg/day led to a higher complete molecular response rate (28% compared to 16%), longer duration of response (79% compared to 57% at 12 months), time to disease progression (67% compared to 44% at 12 months), and overall survival (78% compared to 65% at 12 months) with no clinically relevant increase in toxicity (Table 1). With regard to patients in the chronic phase of CML, a further higher dose of 400 mg twice daily has led to a 38% complete molecular response rate, which repre-

**TABLE 1 Annual Event Rates in Patients after Achievement of Complete Cytogenetic Response on First-Line Imatinib**

| Years after Complete Cytogenetic Response | All Events Inclusive of Deaths and Loss of Response (%) | Progression to Accelerated or Blast Phase (%) |
|---|---|---|
| 1 | 5.5 | 2.1 |
| 2 | 2.3 | 0.8 |
| 3 | 1.1 | 0.3 |
| 4 | 0.4 | 0 |

*Source*: From ref. 16.

sents a sixfold increase over initial studies [19]. Patients that are started on 400 mg twice daily that are diagnosed to be in the chronic phase of CML with an estimated 2-year survival rate is 94%. During a median follow-up of 15 months no patient in the high-dose arm progressed to the accelerated or the blast phase [19]. However, there are some studies that indicate that the benefit obtained from increasing the dose of imatinib is suboptimal. The gains need to be weighed against a higher toxicity profile and patient compliance [20]. Plasma trough levels of imatinib at steady state may be a prognostic factor for clinical responses in patients with CML as they have shown to correlate with both cytogenetic and molecular responses [21, 22].

### 1.6 Side Effects

Side effects that have been noted with imatinib include nausea (50–55%), vomiting (17–41%), edema and fluid retention (41–59%), neutropenia (17–40%), thrombocytopenia (9–33%), elevated liver enzymes (5–14%), diarrhea (15–21%) and fatigue (17–20%) [1, 16]. There is evidence of the increased incidence of toxic effects with doses of imatinib greater than 800 mg per day. Most grades 3–4 toxicities have been noted to occur early in treatment with imatinib (Table 2).

### 1.7 Resistance

Imatinib has shown excellent responses in terms of symptom control and hematologic parameters [2]. However, a significant proportion of patients are resistant to imatinib. Patients are either primarily resistant or develop resistance later on after initially showing a response to imatinib. This has been attributed to development of cytogenetic resistance in leukemic cells [23]. Overall relapse rate for patients with newly diagnosed CML are higher in patients with accelerated and blast-phase disease versus chronic-phase disease [24]. Relapse rate is lower for patients achieving complete cytogenetic response. In patients started on imatinib during the early chronic phase of CML, resistance was noted to emerge only in 16% of the patients at 42 months of follow-up. However, 73 and 95% of the patients develop resistance at 48 months of follow-up, initially in the accelerated and blast phases of CML, respectively. Patients in relapse need new therapies, which has pushed development for new agents to circumvent imatinib resistance [25].

Different mechanisms for resistance have been identified [26]. Mutations in the kinase domain of BCR-ABL are the predominant mechanisms underlying drug resistance. Another mechanism is the amplification of the BCR-ABL fusion gene. A third mechanism of resistance are possibly BCR-ABL-independent mechanisms, possibly related to the activation of the SRC family of kinases or additional molecular events. Point mutations in BCR-ABL kinase domain restrict its ability to adopt an inactive conformation. Mutations in BCR-ABL kinase domain confer varying degrees of resistance to imatinib. In select cases, dose escalation of imatinib may overcome mutation-based resistance. But this has not been seen with mutation T3151 of the BCR-ABL kinase domain [25]. (See Fig. 4.)

Many avenues in overcoming resistance to imatinib have been pursued. One avenue has been to modify imatinib in such a way that the drug binds more tightly, which has been accomplished by Novartis in designing

**Figure 4** Varying degrees of resistance to imatinib from mutations in BCR-ABL kinase domain [27].

**TABLE 2 Grade 3–4 Toxicity to First-Line Imatinib**

| | Overall Incidence | Onset after 2 years | Onset after 4 years |
|---|---|---|---|
| Toxicity | Percentage of Patients | | |
| Neutropenia | 16.7 | 3.7 | 1.0 |
| Thrombocytopenia | 8.9 | 1.5 | 0.2 |
| Anemia | 4.4 | 1.8 | 0.5 |
| Elevated liver Enzymes | 5.3 | 0.4 | 0 |
| Other side effects | 16.9 | 4.8 | 1.7 |

**Figure 5** (A) Surface representations of crystal structures of ABL kinase in complex with imatinib, nilotinib, and dasatinib. (B) Comparison of the different binding modes of three ABL inhibitors: imatinib (left), nilotinib (middle), and dasatinib (right) [28].

nilotinib. Another approach has been the development of entirely different compounds, which was done by Bristol Myers Squibb with dasatinib, which was based on finding that *SRC* inhibitors also inhibit ABL kinase and most imatinib-resistant mutations. Both nilotinib and dasatinib are more potent inhibitors than imatinib, however, they are not active against T3151 mutation. Both dasatanib and nilotinib constitute second-generation drugs. Furthermore, there is a third generation of drugs designed to overcome resistance such as conferred by the T3151 mutation.

## 2 SECOND-GENERATION TYROSINE KINASE INHIBITORS

### 2.1 Nilotinib

Nilotinib (Tasigna) is a second-generation tyrosine kinase inhibitor developed with the intention of treating patients with CML who have developed resistance to imatinib. The chemical structure of nilotinib is 4-methyl-*N*-[3-(4-methylimidazol-1-yl)-5-(trifluoromethyl)phenyl]-3-[(4-pyridin-3-ylpyrimidin-2-yl)amino]benzamide. It is a high-affinity aminopyrimidine-based ATP-competitive inhibitor that decreases proliferation and viability of wild-type BCR-ABL and also cells that express BCR-ABL, which is resistant to imatinib in vitro. (See Fig. 5.) Imatinib-resistant Bcr-Abl mutant-expressing cells in vitro selectively inhibit BCR-ABL autophosphorylation. In addition nilotinib is shown to be a greater than 30-fold more potent inhibitor of wild-type BCR-ABL compared to imatinib in a wide range of CML-derived and transfected cell lines [28, 29].

Not only does nilotinib bind more tightly to BCR-ABL, it has been designed to override resistance caused by mutations. Like imatinib, nilotinib binds to the inactive conformation of the ABL tyrosine kinase, with P-loop folding over the ATP-binding site, and the activation loop blocking the substrate binding site, to disrupt the ATP-binding site and inhibit the catalytic activity of the enzyme. Although nilotinib maintains activity against a majority of imatinib-resistant mutants, it has no significant activity against the T315I mutant BCR-ABL-expressing cell because nilotinib binds closely to the T315 residue inside the BCR-ABL structure similar to imatinib. There is also resistance noted in mutations affecting the P-loop region of BCR-ABL kinase [30].

***Clinical Efficacy*** In a dose-escalating phase I study, a total of 109 patients with imatinib-resistant chronic myelogenous leukemia (CML) in different phases of the disease and Ph+ ALL were treated with nilotinib for up to 385 days [31]. The maximum tolerated dose was determined to be 600 mg twice a day. Side effects noted were myelosuppression, mild–moderate skin rash, and

transient indirect hyperbilirubinemia. In this study, nilotinib was not associated with the edema frequently associated with imatinib. Among patients with chronic-, accelerated-, and blast-phase CML, hematological responses were achieved in 92, 72, and 39%, respectively. Cytogenetic responses were noted in 53, 48, and 27% of patients. The best responses were seen at doses greater than 400 mg once a day and with 400 mg twice a day. In a phase II trial that was designed to characterize the efficacy and safety of nilotinib (400 mg twice daily) with hematologic response as primary efficacy endpoint in patients with accelerated-phase CML who are noted to be resistant and/or intolerant to imatinib, 119 patients were enrolled and had a median duration of treatment of 202 days (range 2–611). A hematologic response was observed in 47% of the patients. Major cytogenetic response was observed in 29% of the patients. Overall survival rate among the 119 patients after 12 months of follow-up was 79%. Nonhematologic adverse events were noted to be mild to moderate. Severe peripheral edema and pleural effusions were not observed. The most common severe hematologic adverse events were thrombocytopenia (35%) and neutropenia (21%) [32]. In one phase II open-label study of patients in chromic-phase CML, 400 mg nilotinib was administered orally twice daily to 280 patients after imatinib failure or intolerance. Patients had at least 6 months of follow-up. At 6 months, the rate of major cytogenetic response was 48%; complete cytogenetic response was noted in 31% and partial response in 16% of the patients. The estimated survival at 12 months was calculated to be 95%. Nilotinib was effective in patients harboring BCR-ABL mutations associated with imatinib resistance (except T315I) and also in patients with a resistance mechanism independent of BCR-ABL mutations. Adverse events were mostly mild to moderate, and there was minimal cross intolerance with imatinib. Grades 3 to 4 neutropenia and thrombocytopenia were observed in 29% of patients; pleural or pericardial effusions were observed in 1% [31].

Nilotinib has substantial clinical utility in rescuing patients who develop imatinib resistance due to point mutations and could potentially be used as a single agent in patients at risk for progression. There are newer studies that suggest both nilotinib and dasatinib can safely be used as first-line medications in patients with chronic-phase CML [33, 34].

Additionally, there is growing interest in testing the hypothesis that administration of multiple ABL kinase inhibitors in early-phase patients, such as nilotinib, dasatinib, and imatinib, could be used to delay or prevent the emergence of drug-resistant clones. However, since the T315I mutation of BCR-ABL is highly resistant to imatinib, nilotinib, and dasatinib, this approach needs to be extended to include inhibitors of T315I BCR-ABL to prevent this mutation from becoming more prevalent. The failure of some patients to respond to nilotinib, especially those with more advanced disease, might arise due to the development of new mutations that impede the interaction between nilotinib and BCR-ABL. Thus, the identification and characterization of BCR-ABL point mutants conferring resistance to nilotinib will assist in the prediction of patient responses to nilotinib, identifying combination partners, as well as in the design and development of novel inhibitors of BCR-ABL that can override resistance to such mutants. The U.S. FDA recently approved nilotinib (Tasigna) for treatment of Philadelphia chromosome-positive chronic myeloid leukemia in adult patients whose disease has progressed or who cannot tolerate other therapies, which included imatinib.

### 2.2 Dasatinib

Dasatinib (Sprycel) is considered a second-generation tyrosine kinase inhibitor used in the treatment of CML. The chemical structure of dasatinib is *N*-(2-chloro-6-methylphenyl)-2-[[6-[4-(2-hydroxyethyl)-1-piperazinyl]-2-methyl-4-pyrimidinyl]amino]-5-thiazole carboxamide monohydrate. In in vitro studies it is active against all tested ABL mutations, except for T315I like both imatinib and nilotinib. Dasatinib has demonstrated high efficacy in phase I and II studies in patients with CML following the failure of imatinib therapy. In addition to binding ABL kinase with less stringent conformational requirements than imatinib, dasatinib has the ability to be a potent SRC kinase inhibitor as well. Therefore, dasatinib is considered a dual BCR-ABL and SRC family tyrosine kinases inhibitor. SRC kinase activation has been linked to BCR-ABL-mediated leukemogenesis and CML progression. It has been approved by the FDA for use in patients with CML after imatinib treatment and Ph+ ALL [35].

The drug is named after the inventor chemist, Jagabandhu Das, who co-discovered it while working at Bristol Myers Squibb [36]. It binds to both inactive and active conformations of BCR-ABL [37]. It is 325-fold more potent at inhibiting BCR-ABL kinase activity than imatinib [38].

It is an oral medication. Its oral bioavailability varies from 14 to 34%, probably as a result of a combination of incomplete absorption and high first-pass metabolism. Pharmacokinetic data suggest that dasatinib is mainly cleared by oxidative metabolism, which involves the CYP3A4 enzyme system in the liver [35, 39]. The terminal half-life is noted to be 3–5 h. Pharmacodynamic data indicates there is inhibition of CrkL which is a downstream substrate of BCR-ABL kinase, which is

more prolonged compared to the relatively short half-life of dasatinib, which indicates that more frequent dosing with dasatinib may not be necessary [39].

***Clinical Efficacy*** In one phase I, open-label, dose escalation study in patients with CML or Ph+ ALL who could not tolerate or were resistant to imatinib, dasatinib was evaluated. Complete hematologic response was achieved in 92%, and major cytogenetic response was seen in 45% of the patients. Most of the complete hematologic responses occurred at doses of 50 mg/day, whereas most of the cytogenetic responses required higher doses. Responses were maintained in 95% of patients with chronic-phase disease and in 82% of patients with accelerated-phase disease. In the case of CML responses were seen to occur at all genotypes except for T315I mutation. Myelosuppression was seen as a major side effect, which was reversible and not dose limiting. Grades 3–4 neutropenia occurred in 45% of the patients [35]. A maximum tolerated dose was not reached, leading to the adoption of a schedule of 70 mg of dasatinib twice a day in some phase II studies.

In a phase II study, 387 patients with chronic-phase CML and imatinib resistance or intolerance were enrolled. At a median follow-up of 15 months, 91% of patients were noted to have achieved complete hematologic responses that were previously resistant to imatinib. Of patients resistant to imatinib, 52 and 40 had achieved a major cytogenetic response and complete cytogenetic remission, respectively, compared with 80 and 75% of patients who were intolerant of imatinib [40]. The occurrence of a major cytogenetic response was similar in patients with and without mutations and in the 72% of patients who had received imatinib at doses of 600 mg or higher before starting dasatinib. In phase II clinical trials at 8-month follow-up, dasatinib induced major hematologic responses in 34 and 31% of myeloid blast crises and lymphoid blast crises CML patients and major cytogenetic responses in 31 and 50% of these patients, respectively. Most (86%) of these major cytogenetic responses were complete cytogenetic responses. Responses were rapid and durable: 88 and 46%, respectively, of myeloid blast crises and lymphoid blast crises CML patients achieving major hematologic response had not experienced disease progression at the 8-month follow-up. Response rates were similar in patients with and without BCR-ABL mutations known to confer resistance to imatinib. Recent phase III data has demonstrated that treatment with 100 mg per day of dasatinib is associated with a most favorable risk–benefit ratio compared to other regimens including 70 mg twice a day and 140 mg once a day [41].

Dasatinib overall has been noted to be well tolerated. Nonhematologic adverse events were mild to moderate. Cytopenias were common and could be managed by dose modification [42]. Fluid retention seems to be the most troublesome nonhematogical toxic effect of dasatinib, which includes pleural effusions. In one study 35% of patients treated with dasatinib developed pleural effusions that were usually exudative, some reaching grade 3 or 4 toxicity, and were mainly in participants who received daily doses of 140 mg of dasatinib or greater [40, 43]. Dasatinib may also be active after failure with treatment with both imatinib and nilotinib [44]. In one study patients who had demonstrated resistance to standard dose of imatinib 400–600 mg/day in chronic-phase CML were treated with either a maximum dose of dasatinib of 90 mg twice daily or a high dose of imatinib of 800 mg/day. Patients were followed for a median of 15 months. Patients taking dasatinib versus imatinib had a higher incidence of complete hematologic response of 93 versus 82% and a higher major cytogenetic response of 52 versus 33%, and complete cytogenetic response of 40 versus 16% [15]. This indicates that it is preferable to switch to dasatinib right away with patients with imatinib resistance or failure rather than increasing the dosage of imatinib to evaluate for response. Although both nilotinib and dasatinib show encouraging preliminary findings, the concern exists that their use will result in the identification of new mutations in the ABL-kinase domain.

Several groups have now reported clinical resistance to dasatinib in association with persisting or emerging mutations. Recent studies have identified F317L/I and T315I as the most frequent mutations. In addition BCR-ABL with V299L and V304D are also shown to be resistant to dasatinib [35]. As mentioned earlier, in many patients mechanisms other than kinase domain mutations are likely responsible for disease resistance.

### 2.3 Bosutinib

Bosutinib, previously known as SKI-606, is a 4-anilino-3-quinoline carbonitrile dual inhibitor of SRC and ABL, which is orally active and has antiproliferative activity against CML [45]. It is currently being developed by Wyeth. This drug has no activity against the tyrosine kinase receptors for platelet-derived growth factor [the inhibition of which is thought to account for the fluid retention noted with other tyrosine kinase inhibitors (TKIs)] and cKit. Its inhibitory activity against BCR-ABL is 200 times more potent than imatinib. It inhibits a wide variety of BCR-ABL kinase mutants, except T315I [45, 46].

Bosutinib is known to reduce vascular endothelial growth factor-mediated vascular permeability and tumor-cell extravasation, and its effect on cell-to-cell interactions between tumor cells and host cells might be

crucial for its in vivo efficacy. Phase I trials have shown the dose to be 500 mg once a day for testing in phase II trials. Recent preliminary data from a phase II study for assessable patients with chronic-phase CML, who were resistant to imatinib, showed that 74% achieved complete hematological response, 42% achieved major cytogenetic response with 33% of patients receiving complete cytogenetic response on bosutinib with a median duration of treatment of 5.1 months. Among patients who had previously received nilotinib and dasatinib, 38% achieved complete hematologic response, whereas 25% were able to achieve major cytogenetic response. Major hematologic toxicities noted were thrombocytopenia in 9% of the patients, neutropenia in 8%, and anemia in 1% of the patients. Most common side effects noted are gastrointestinal but are mild and transient [47]. In patients with accelerated-phase and blast-phase CML, complete hematologic response has been noticed in 29 and 25% of the patients, respectively, with median duration of treatment with bosutinib for 2.7 months [48]. There is a potential for synergistic effect with imatinib based on in vitro studies [46].

## 3 THIRD-GENERATION TYROSINE KINASE INHIBITORS

### 3.1 MK0457

The aurora family of serine–threonine kinases is essential for mitotic progression. All members of this family have identifiable ATP-binding sites and have been linked to tumor genesis via induction of genetic instability. MK0457, previously known as VX680, is an example of an aurora kinase inhibitor and exerts antiproliferative and proapoptotic activity in several tumor cell lines. For example, cells treated with MK0457 enter mitosis and proceed through the S-phase but do not divide. Furthermore, MK0457 binds to the active conformation of BCR-ABL and is noted to have activity against the T315I mutation. It is also an inhibitor of Janus kinase 2. This inhibitor has entered clinical studies of imatinib-resistant CML and Philadelphia-chromosome-positive acute lymphoblastic leukemia. Initial reports show that patients with resistant disease associated with the T315I mutation had hematological responses, and in some of these patients, the concentration of the mutant clone decreased. These reported cases are the first clinically observed activity of a kinase inhibitor against the T315I phenotype of CLL [49].

### 3.2 Adaphostin

Adaphostin (also known as NSC680410) is a tyrophostin inhibitor that was designed to compete for the ATP substrate rather than ATP with BCR-ABL. Adaphostin has the ability to select CML cells over healthy cells in clonogenic assays and induces apoptosis in other leukemic cells, which suggests that its effect might not be entirely BCR-ABL specific. Another way adaphostin may be effective may be related to an increase in reactive oxygen species, which amplifies the effect of adaphostin. Adaphostin also downregulates the BCR-ABL protein. This effect is not prevented by antioxidants, thereby implying that the downregulation of BCR-ABL precedes or parallels the production of reactive oxygen species. It has been found effective against wild-type BCR-ABL and all known mutations including T315I.

### 3.3 XL228

XL228 is a protein kinase inhibitor. It has potent activity against different isoforms of BCR-ABL including T315I. It also has activity against IGF1R and SRC. It has shown to modulate CrkL activity, indicating downstream inhibition of BCR-ABL signaling in T315I isoforms. Preliminary phase I results show that XL228 is well tolerated. It is given as an intravenous infusion. It has a mean terminal half-life ranging from 15 to 40 h. XL228 is a promising agent for the treatment of CML and Ph+ ALL that is resistant to earlier generation tyrosine kinase inhibitors [50].

### 3.4 AP24534

AP24534 is an orally active BCR-ABL inhibitor. It is shown to inhibit unmutated and mutated isoforms, particularly T315I of BCR-ABL. It is inactive against aurora kinases. It also inhibits the Flt3, SRC, VEGFR, and FGFR family of kinases, which may contribute to its potency toward treating CML. The in vitro kinase profile suggests that the inhibition of BCR-ABL is the main mechanism for activity against BCR-ABL models. Based on promising preliminary studies, phase I studies are currently planned to assess the safety and tolerability of this agent [51].

### 3.5 INNO406

INNO406, also known as CNS9 or NS187, is 25–55 times more potent than imatinib against the ABL kinase and also inhibits LYN, a protein that has been implicated in the progression to blast phase [23]. However, this drug is also not active against the T315I mutation. INNO406 is orally bioavailable in a murine model and seems to be a competitive inhibitor of ATP [52]. Initial phase I trials have shown that it is well tolerated. It has been tested in patients who have been treated with imatinib and the second-generation agents nilotinib and dasat-

inib. The recommended phase II dose is likely to be 240 mg twice daily. Up to now, both hematological and cytogenetic responses have been shown. This drug is likely to be a competitor for first-line or second-line treatment of CML, rather than third-line treatment.

## 4 SUMMARY

The discovery of imatinib has revolutionized the treatment of CML. It is a classic example of drug development based on the identification of a common molecular target involved in a signaling pathway. It was the first medication that inhibited a particular molecular target in the cell to treat a cancer type instead of as in earlier chemotherapy drugs that nonspecifically target rapid dividing cells. It is considered such a breakthrough that it has been featured on the cover of *Time* magazine after approval by the FDA [53]. Imatinib has demonstrated significantly lower toxicity while having significant effectiveness compared to earlier therapies; however, it is not considered curative. Furthermore, issues with imatinib resistance have emerged [54]. This has led to the development of more targeted therapies to overcome resistance. Dasatinib and nilotinib have received FDA approval, both of which are effective in treating patients who have demonstrated resistance or intolerance to imatinib. Further drugs are in development that show promise to be even effective in patients resistant to dasatinib and nilotininb as well. This will provide further options and even improved outcomes in patients being treated for CML.

## 1 INTRODUCTION

The continued evolution of endocrine therapy has contributed to many therapeutic options for patients with breast cancer. In 1998, Oxford overview demonstrated that the selective estrogen receptor modulator (SERM) tamoxifen (TM) was equally effective in pre- and postmenopausal breast cancer patients. Development of aromatase inhibitors (AIs) added a new option in addition to SERMs for the treatment of breast cancer.

The landmark study of anastrozole (Arimidex), tamoxifen alone, or TM in a combination (ATAC) trial by Michael Baum presented at the San Antonio Breast Cancer Symposium in 2001 marked a turning point in breast cancer therapy. In the ATAC trial anastrozole had a better disease-free survival rate compared to TM when used in postmenopausal patients. Since the publication of the ATAC trial [1], several other trials have looked at the role of aromatase inhibitors such as letrozole [Breast Internation Group (BIG 98)] and exemestane [Intergroup Exemestane Study (IES)] in adjuvant therapy for postmenopausal breast cancer patients. All these studies have confirmed that AIs are superior to tamoxifen and have fewer side effects.

## 2 BIOCHEMISTRY

The two main circulating estrogens in the body are estrone and estradiol, derived from cholesterol. By inhibiting the enzymes, which act on earlier steps in the branching pathway of steroidogenesis, it is possible to have consequences of undesirable impact on the production of other physiologically necessary and important hormones such as aldosterone and cortisol. The conversion of androgens to estrogens occurs at peripheral sites such as in muscle, fat, liver, and also in breast tumor cells. Aromatase is a cytochrome P450 enzyme that has both a steroid-binding and iron-containing site.

Androstenedione is the substrate for aromatase and it is linked to the enzyme's steroid-binding site. Based on this structural relationship, there are two reasonable and effective ways to inhibit aromatase, either by occupying the steroid-binding site of the enzyme with a compound or by binding the iron with nitrogen-containing compounds such as aminoglutethimide. Since aromatase catalyzes the last step in estrogen production, it makes an ideal target for the development of selective and potent inhibitors.

The comparative efficacy of AIs may be assessed in two ways. The conversion measurement of androgens into estrogens provides direct evidence of enzymatic activity. On the other hand, measurement of suppression of plasma estrogens provides indirect evidence of enzymatic aromatase activity. Drug metabolism (half-life) and tissue distribution are the two main factors for in vivo measurements of the biochemical efficacy of a compound. Intergeneration and intrageneration significant differences have been reported in the time to reach steady-state plasma levels, half-life, elimination, and in the interaction with several cytochromes (CXP) of the P450 superfamily. Aromatase inhibition and estradiol

**TABLE 1 Classification of Aromatase Inhibitors**

| Generation | Type I (Steroidal Inactivator) | Type II (Nonsteroidal Inhibitor) |
|---|---|---|
| First | None | Aminogluthethimide (Cytadren) |
| Second | Formestane (Lentaron) | Fadrozole<br>Rogletimide |
| Third | Exemestane (Aromasin) | Anastrozole (Arimidex)<br>Letrozole (Femara)<br>Vorozole |

suppression show good correlation and are consistently higher for third-generation AIs when compared with first- and second-generation AIs. (See Figs. 1–3.)

## 3 CLASSIFICATION

Based on the mechanism of action and chronologic order of development along with relative potency, AIs can be divided into two types and three generations, respectively (Table 1). AIs represent several generations of development, and in each step the evolution presented a compound with increase potency and specificity. The third-generation AIs are drugs of immense potential and undoubtedly play a major role in the management of postmenopausal women with hormone-dependent breast cancer.

## 4 CLINICAL PHARMACOLOGY

The type I or steroidal inactivators are derivatives of androstenedione, which is the aromatase physiological substrate. Type II or nonsteroidal inhibitor compounds are derived by phenobarbitone (e.g., aminoglutethimide) or may be characterized by the imidazole/triazole structure. Type I AIs bind covalently to the enzyme, causing its irreversible inactivation. But the nonsteroidal compounds provide reversible binding. First- and second-generation AIs are characterized by lower selectivity and potency in comparison to newer AIs.

Aromatase, a cytochrome P450 enzyme, is involved in catalyzing three consecutive hydroxylation reactions converting C19 androgens to aromatic C18 estrogens. After receiving electrons from nicotinamide adenine dinucleotide phosphate (NADPH)–cytochrome P450 reductase, aromatase converts androstenedione and testosterone, respectively, to estrone and estradiol. Aromatization of androgen is the terminal and rate-limiting step in estrogen production. Abnormal overexpression of aromatase in breast tissue plays a significant part in breast cancer pathogenesis. Under the above circumstances, inhibition of aromatase is a promising and new strategy for reducing growth-stimulatory effects of estrogen in breast cancer pathology. Multiple studies suggest potential endocrine manipulation in the treatment of breast cancer and support adjuvant and sequential systemic treatment including AIs.

Anastrozole provides 70% estradiol reduction after 24 h and 80% after 2 weeks of therapy. Duration of estradiol reduction is about 6 days. It is well absorbed and not affected by food. Plasma protein binding is about 40%. It is metabolized extensively by liver (~85%) via *N*-dealkylation, hydroxylation, and glucuronidation, but the primary metabolite is inactive. Anastrozole is excreted in the urine (10% as unchanged drug; 60% as metabolites). Letrozole is also well absorbed and the absorption is not affected by food. Its plasma protein binding is weak. It is metabolized through liver by CYP3A4 and 2A6 to an inactive carbinol metabolite. The drug is excreted in the urine (90%; 6% as unchanged drug, 75% as glucuronide carbinol metabolite, 9% as unidentified metabolites).

Exemestane is rapidly but moderately (~42%) absorbed following oral administration. Absorption may increase by another ~40% following a high-fat meal. Plasma protein binding is extensive (90%), pri-

marily to albumin and $\alpha_1$-acid glycoprotein. It is extensively metabolized by liver [oxidation (CYP3A4) of methylene group], reduction of 17-keto group with the formation of many secondary metabolites, but the metabolites are inactive. The drug is excreted in the urine (39–45% as metabolites, <1% as unchanged drug) and feces (36–48%).

## 5 DESCRIPTION OF AI IN BRIEF

The first-generation inhibitor refers to the nonsteroidal inhibitor aminoglutethamide (AG). The reports of adrenal insufficiency led to withdrawal from clinical use. AG is less specific and inhibits other CYP450 enzymes involved in cortisol and aldosterone biosynthesis, which results in toxicity. Its efficacy in inhibiting aromatase activity stimulated the development of various new inhibitors during the 1980s and 1990s. The second-generation inhibitors are the imidazole derivative fadrozole and the steroid analog formestane. Fadrozole is more selective and potent than AG, but it still has inhibitory effects on progesterone, aldosterone, and corticosterone production. Formestane was the first selective AI to be used clinically and was effective and well tolerated, but its requirement of intramuscular administration limited its clinical use.

The third-generation inhibitors were developed in the early 1990s. Anastrozole and letrozole are nonsteroidal derivatives characterized by a triazole functional group that interacts with the heme prosthetic group of aromatase and act as competitive inhibitors with respect to the androgen substrates. Exemestane is a steroidal and mechanism-based inhibitor that is catalytically converted into a chemically reactive species, leading to irreversible inactivation of aromatase. These are widely used as the first-line drugs in the endocrine treatment of hormone-dependent postmenopausal breast cancer in patients. Anastrozole, letrozole, and exemestane are administered orally at 1, 2.5, and 25 mg once daily, respectively. Compared to the first- and second-generation inhibitors, the third-generation inhibitors produce greater clinical benefit with near-complete specificity at clinical use.

## 6 AROMATASE INHIBITORS IN POSTMENOPAUSAL PATIENTS

### 6.1 Anastrozole in Metastatic Breast Cancer

The Tamoxifen or Anastrozole Randomized Group Efficacy and Tolerability (TARGET) study was a randomized, double-blind trial that compared TM to anastrozole as front-line treatment in advanced breast cancer. All the available data from this study and a North American study conducted at the same time were combined and analyzed. At a median follow-up of 43.7 months, mortality was 56% in the anastrozole group and 56.1% in the TM group. Both treatment arms were well tolerated, however, there were less gynecological complications (1% vs. 2.5%) and thromboembolic phenomena (5.3% vs. 9%) in the anastrozole arm. It is to be concluded that anastrozole provided similar efficacy as tamoxifen but appeared to be better tolerated.

### 6.2 Anastrozole in Adjuvant Therapy

The ATAC trial compared 5 years of anastrozole versus 5 years of TM versus the combination of anastrozole and TM in postmenopausal women as an adjuvant therapy. After 68 months of follow-up, anastrozole showed significantly improved disease-free survival (hazard ratios (HR) 0.87, 95% CI 0.78–0.97, $P = 0.01$). A significant reduction in contralateral breast cancer (42% reduction, 95% CI 12–62, $P = 0.01$) and distant metastases (HR 0.86, CI 0.74–0.99, $P = 0.04$) were observed.

### 6.3 Anastrozole in Switching Adjuvant Therapy

The Italian Tamoxifen Anastrozole (ITA) trial was a prospective randomized study evaluating the benefit of switching from TM to anastrozole in adjuvant scenarios. After 2–3 years of TM therapy, women were randomly assigned to receive an additional 2–3 years of TM or anastrozole. At median follow-up of 36 months, event-free and recurrence-free survival was significantly better in the anastrozole group (HR 0.35, 95% CI 0.2–0.63, $P = 0.0002$; HR 0.35, 95% CI 0.18–0.68, $P = 0.001$) and local disease control was also improved in anastrozole group (HR 0.15, 95% CI 0.03–0.65, $P = 0.003$).

The Arimidex–Nolvadex (ARNO) and the Austrian Breast and Colorectal Cancer Study Group (ABCSG) trials both provided the data on switching to anastrozole after 2 years of TM. After the combined analysis, at median follow-up of 28 months, event-free survival was better in the anastrozole group in comparison to patients who stayed on TM (HR 0.60, 95% CI 0.44–0.81, $P = 0.0009$).

The above-mentioned three trials clearly showed superiority of anastrozole over tamoxifen in postmenopausal women with breast cancer. Based on these findings, the Food and Drug Administration (FDA) approved the use of anastrozole 1 mg p.o. daily in metastatic breast cancer in January 1996 and as an adjuvant therapy for early breast cancer in September 2002.

### 6.4 Letrozole in Metastatic Breast Cancer

The International Letrozole Breast Cancer Group conducted a trial that compared letrozole to TM as first-line therapy in postmenopausal women with advanced breast cancer. Time to progression and time to treatment failure were significantly better in the letrozole group (9.4 vs. 6 months, $P < 0.0001$; 9.0 vs. 5.7 months, $P < 0.0001$, respectively). Objective response rate were also significantly higher in the letrozole group (32% vs. 21%, $P = 0.0002$). A trend toward improved overall survival for women in the letrozole group was observed, but this was not statistically significant (34 vs. 30 months, $P = 0.53$).

### 6.5 Letrozole in Adjuvant Therapy

The BIG 1-98 Collaborative Group was a phase III, randomized, double-blind study comparing letrozole and TM each as monotherapy versus sequential administration. Disease-free survival was significantly improved in the letrozole arm compared to TM (HR 0.81, 95% CI 0.7–0.93, $P = 0.003$) along with distant recurrence (HR 0.73, 95% CI 0.6–0.88, $P = 0.001$). Five-year estimates of disease-free survival were 81.4% for the TM arm and 84% for the letrozole arm. Subgroup analyses showed better response in patients on letrozole with node-positive disease (HR 0.71, 95% CI 0.59–0.85, $P < 0.001$) and patients who received letrozole and chemotherapy (HR 0.70, 95% CI 0.54–0.92, $P = 0.01$).

### 6.6 Letrozole in Extended Adjuvant Therapy

The National Cancer Institute of Canada MA-17 study is a phase III randomized, double-blind, placebo-controlled trial that randomized postmenopausal women to receive an additional 5 years of letrozole versus placebo who completed about 5 years of TM. The first interim analysis showed the estimated 4-year disease-free survival to favor letrozole (93% vs. 87%, HR 0.57, 95% CI 0.43–0.75, $P = 0.00008$). Subgroup analyses demonstrated that letrozole was as effective in node-negative disease (HR 0.47, $P = 0.005$) as it was in node-positive disease (HR 0.60, $P = 0.003$). Based on the above data, FDA approved letrozole 2.5 mg for extended adjuvant therapy in breast cancer treatment.

### 6.7 Exemestane in Switching Adjuvant Therapy

The IES is an international, double-blind, phase III randomized switching trial that involves TM for 5 years versus exemestane after at least 2 years, and no more than 3 years and 1 month of TM. After a median follow-up of 37.4 months, an interim analysis showed improved disease-free survival in women who switched to exemestane (HR 0.73, 95% CI 0.62–0.86, $P = 0.0001$). Exemestane 25 mg daily is approved by the FDA for use in the adjuvant setting after 2–3 years of tamoxifen.

## 7 CONCLUSION ON AIS IN BREAST CANCER THERAPY

The American Society of Clinical Oncology recommends that an AI should be included in the adjuvant treatment of postmenopausal women with hormone receptor-positive breast cancer. Treatment options include 5 years of an AI versus sequential therapy with TM (combination of 2–3 years or 5 years) followed by an AI for 2–3 or 5 years. Patients who cannot tolerate TM should be offered an AI. After progression on TM or AI, consideration could be given to fulvestrant or megestrol acetate. (See Table 2.)

## 8 LACK OF CROSS RESISTANCE

The first published data on lack of cross resistance between different AIs was reported in advanced breast cancer patients who showed clinical response to formestane after progression on AG. Lonning et al. showed that after 8 weeks of exemestane, the overall response rate was 8.1% in patients previously treated with AG and 4.8% in those treated with other nonsteroidal AIs. Exemestane following AG was associated with enhanced aromatase inhibition. There was no difference in any type of serum estrogen with the switch from other nonsteriodal AIs to exemestane. Several other studies have addressed this issue, providing the evidence that significant benefit can be achieved with exemestane after second- and third-generation nonsteroidal AIs.

## 9 SIDE EFFECTS

It is obvious that AIs have an adverse reaction profile like other endocrine therapies. It can mimic menopausal symptoms due to depletion of estrogen and are the same, such as hot flashes and sweating. Adverse reactions related to AIs include stomach upsets (nausea, vomiting, diarrhea), rash, and arthralgia. First-generation AI was poorly tolerated and could cause drowsiness, fever, and inhibition of cortisol synthesis. Formestane is well-tolerated as a treatment but can cause a local reaction around the injection site. These drugs were also found to be better tolerated than TM and were associated with lower incidences of endometrial cancer, vaginal bleeding and discharge, cerebrovascular events,

**TABLE 2 FDA-Approved Indications, Doses, and Duration of Commonly Used AIs**

| AIs | FDA-Approved Indications | Doses/Duration |
|---|---|---|
| Anastrezole | 1. Postmenopausal with hormone receptor-positive early breast cancer<br>2. Postmenopausal with hormone receptor-positive early breast cancer after 2–3 years of TM therapy<br>3. Locally advanced or metastatic breast cancer (hormone receptor-positive or status unknown)<br>4. Postmenopausal women with metastatic disease progression after TM therapy | 1 mg orally daily; maximum duration up to 5 years |
| Letrozole | 1. Postmenopausal with hormone receptor-positive early breast cancer<br>2. Postmenopausal with hormone receptor-positive early breast cancer after 5 years of TM therapy<br>3. Locally advanced or metastatic breast cancer (hormone receptor-positive or status unknown)<br>4. Postmenopausal women with metastatic disease progression after antiestrogen therapy | 2.5 mg orally daily; maximum duration up to 5 years |
| Exemestane | 1. Postmenopausal women with disease progression after TM therapy (orphan drug)<br>2. Postmenopausal with hormone receptor-positive early breast cancer after 2–3 years of TM therapy<br>3. Postmenopausal with hormone receptor-positive early breast cancer who are switched to exemestane for completion of total of 5 consecutive years of adjuvant hormone treatment | 25 mg orally after meal daily; maximum duration up to 5 years |

venous thromboembolic events, and hot flashes. (Se Table 3.)

There were significantly less endometrial malignancies (0.2% vs. 0.8%, $P = 0.02$), ischemic cerebrovascular events (2% vs. 2.8%, $P = 0.03$), vaginal bleeding/discharge (8.9% vs. 23.4%, $P < 0.0001$), venous thromboembolic events (2.8% vs. 4.5%, $P = 0.0004$), and hot flashes with anastrozole compared to tamoxifen. There was a nonsignificant trend toward more ischemic cardiovascular disease in the anastrozole group (4.1% vs. 3.4%, $P = 0.1$). Women who switched to anastrozole had significantly more gastrointestinal side effects and lipid metabolism disorders than those on tamoxifen (7.9% vs. 2.7%, $P = 0.3$ and 9.3% vs. 4%, $P = 0.04$, respectively). Patients who remained on tamoxifen had more significant gynecological abnormalities, including endometrial carcinoma (11.3% vs. 2%, $P = 0.0002$). Letrazole showed a significantly increased risk of thromboembolic events (3.5% vs. 1.5%, $P < 0.001$), hot flashes, and vaginal discharge in comparison to tamoxifen. Women on letrozole also developed fewer invasive endometrial cancers (0.1% vs. 0.3%, $P = 0.18$).

**TABLE 3 Common Side Effects with Commonly Used AIs**

| Side Effects | Anastrozole (%) | Letrozole | Exemestane |
|---|---|---|---|
| Hot flashes | 12–36 | 5–50 | 13–21 |
| Nausea/vomiting | 11–19 | 9–17 | 6–15 |
| Fatigue/weakness | 7–18 | 4–34 | 8–22 |
| Bone pain | 6–20 | 8–22 | 7–21 |
| Arthalgia | 2–15 | 8–22 | 15–29 |
| Headache | 7–19 | 4–20 | 5–18 |
| Hypertension | 2–13 | 3–11 | 5–15 |
| Mood disturbance | 11–19 | 2–12 | 4–10 |

## 10 SKELETAL EVENTS

In clinical practice, the long-term side effects on the skeletal system should be monitored closely. Multiple trials have included bone side effect profile in the studies (Table 4). In ATAC trial after a median follow-up of 68 months, it has been reported that the clinical fracture rate in the AIs group is significantly higher than the TM group (11% vs. 7.7%, $p < 0.0001$). There was no difference in the rate of hip fractures (1.2% vs. 1.0%, $p = 0.5$) and wrist fractures (2.3% vs. 2.0%, $p = 0.4$). But spine fractures (1.5% vs. 0.9%, $p = 0.03$ and other site fractures (7.1% vs. 4.6%, $p < 0.0001$) rate were higher in the AIs group in comparison to the TM group. After a median follow-up of 60 months, bone mineral density (BMD) changes were adversely affected in the AIs group both in the spine (−6.1 vs. +2.8) and in hip (−7.2 vs. +0.7) (Table 5). Patients on AIs had both

**TABLE 4 Clinical Fracture Rates in Different Trials Using AIs**

| Trial | Follow-up in Months | Primary Agent | Comparator Agent | AIs (%) | Comparator (%) | *P* Value |

H = hip fractures

**TABLE 6 Osteoporosis Rates in Different Trials Using AIs**

| Trial | Follow-up in Months | Primary Agent | Comparator Agent | AIs (%) | Comparator Agent (%) | *P* Value |
|---|---|---|---|---|---|---|
| IES | 31 | Exemestane | Tamoxifen | 7.4 | 5.7 | 0.05 |
| MA 17 | 30 | Letrozole | Placebo | 8.1 | 6.0 | 0.003 |
| Goss et al (2011) [2] | 29 | Letrazole | Placebo | 5.8 | 4.5 | 0.07 |

increased bone resorption (15.5%, 95% CI = 3–25%) and bone formation (20%, 95% CI = 14–25%), whereas patient on TM had both decreased bone formation and resorption.

In the BIG I-98 trial, after a median follow-up of 25.8 months, clinical fracture rate was higher in the AIs group than the TM group (5.7% vs. 4.0%, $p < 0.001$). In the TEAM trial, the AI group had negative changes in BMD both in the spine (–2.75 vs. 1.0, $p = 0.0257$) and in the hip (-2.2 vs. 3.3, $p = 0.012$) in comparison to TM. In all the above-mentioned trials TM was found to prevent bone health. The ABCSG8/ARNO 95 (two different trials with one combined analysis for possible statistical power) found higher clinical fracture rates in the AIs group (2% vs. 1%, $p = 0.015$) and negative BMD change in the spine (–17.4 vs. 11.6, $p < 0.0001$).

Studies have shown that most of the recurrence in hormone receptor-positive breast cancer will occur after 5 years of TM therapy. The MA 17 clinical trial addressed this issue. Letrozole was compared with placebo after 5 years of TM therapy. There was a nonsignificant but higher rate of clinical fracture in the AI group (5.3% vs. 4.3%, $p = 0.25$). But changes in BMD were significantly higher in the letrozole group both in the spine (–5.35% vs. –0.71%, $p = 0.008$) and the hip (–3.6% vs. –0.70%, $p = 0.044$). (See Table 6.)

## 11 TREATMENT OF SKELETAL-RELATED EVENTS WITH AIS

Life-style modification (e.g., smoking cessation, balanced diet, physical activity, regular physical exercise, maintaining ideal body weight), supplementation with calcium (1200 mg/day), and vitamin D (800 IU) are recommended for patients at risk for osteoporosis because these levels prevent decreases in femoral neck BMD and reduce the risk for hip fractures in elderly women. The American Society of Clinical Oncology (ASCO) expert panel recommended breast cancer patients who have evidence of bone destruction on plain radiographs be treated with intravenous pamidronate 90 mg delivered over 2 h or zoledronic acid 4 mg over 15 min every 3–4 weeks. There is insufficient evidence supporting the efficacy of one bisphosphonate over the other, although zoledronic acid is used more widely. If there is an abnormal bone scan and an abnormal computed tomography (CT) or magnetic resonance imaging (MRI) scan showing bone destruction, but normal plain radiographs, starting bisphosphonates is considered appropriate based on the findings in women with lytic or mixed lytic/blastic changes on plain radiographs. It is also not recommended by the ASCO panel to start bisphosphonates in women with only an abnormal bone scan but without evidence of bone destruction on radiographs, CT scans, or MRI. Integrating bisphosphonates in the treatment without evidence of bone metastases even in the presence of other extra-skeletal metastases is not recommended. There should be no change in dosage, infusion time, or interval in patients with a serum creatinine less than 3.0 mg/dL (265 μmol/L). Infusion times less than 15 min with zoledronic acid or less than 2 h with pamidronate should be avoided to preserve renal function. Creatinine should be monitored before each dose of either agent as per FDA labeling instructions. It is not recommended to use any biochemical markers to monitor bisphosphonate response, and therapy should be continued until there are subjective and objective evidences of substantial decline in patient's general performance status.

## 12 CONTRAINDICATION OF AI

Hypersensitivity to AIs or any component of the formulation and pregnancy are the contraindications for AIs use.

## 13 DRUG INTERACTIONS

*CYP3A4 inducers*: May decrease the levels/effects of AIs. Examples of inducers include but are not limited to aminoglutethimide, carbamazepine, efavirenz, fosphenytoin, nafcillin, nevirapine, oxcarbazepine, pentobarbital, phenobarbital, phenytoin, primidone, rifabutin, rifampin, and rifapentine. Dosage adjustment required with potent inducers. Rifampin may decrease exemestane levels.

## 14 NUTRITION AND HERB INTERACTIONS

Plasma levels may be increased by 40% if AIs are taken with a fatty meal. St. John's wort may decrease AI levels. Patient should avoid black cohosh, dong quai in estrogen-dependent tumors.

## 15 PREGNANCY IMPLICATIONS

AIs have been associated with prolonged gestation, abnormal or difficult labor, and increased resorption, reduced number of live fetuses, decreased fetal weight, and retarded ossification in rats. AIs are not indicated for premenopausal women, but if exposure occurred during pregnancy, risk to the fetus and potential risk for loss of the pregnancy should be discussed. Excretion of AIs in breast milk is unknown.

## 16 FUTURE DIRECTIONS

In clinical practice, third-generation AIs are firmly established as effective agents in the therapy for postmenopausal women with advanced and early-stage breast cancer. Some of the new data might also indicate a greater role in preventive settings. The available data, especially information from bone subprotocols have shown an adverse effect of AIs in bone health. But at this time we need more studies to define more clearly the absolute and relative risk of osteoporosis, fractures, and endpoint relation of BMD in this population. Even given all these limitations, oncologist should use AIs where indicated with appropriate and expanded knowledge of the effect of AIs on bones and their timely management. At the same time, bone health should be evaluated and monitored accordingly. Appropriate treatment with diet modification, calcium, vitamin D, and bisphosphonate should be initiated when indicated.

# EVOLUTION OF SELECTIVE ESTROGEN AND ANDROGEN RECEPTOR MODULATORS: STATUS OF CURRENT THERAPY AND NEW DRUG DEVELOPMENT

Gregory T. Wurz and Michael W. DeGregorio

*Department of Internal Medicine, Division of Hematology and Oncology, School of Medicine, University of California, Davis, Sacramento, California*

## 1 BACKGROUND

Selective estrogen and androgen receptor modulators (SERMs and SARMs) are compounds that can act, respectively, as either estrogen receptor (ER) or androgen receptor (AR) agonists or antagonists on a tissue-selective basis. For example, the SERM tamoxifen, which is widely used in the treatment of breast cancer, is an ER antagonist in breast tissue but has agonistic effects in the endometrium. SERMs and SARMs are diverse groups of molecules comprised of structurally unrelated compounds from several different chemical classes. The chemical structures of selected SERMs and SARMs are shown in Figures 1 and 2. Included in Tables 1 and 2 are some of the various chemical classes of SERMs and SARMs as well as some clinically approved and investigational compounds from each class.

### 1.1 How SERMs and SARMs Became a Focus of Drug Development

The search for new contraceptive agents in the 1950s and 1960s led to the development of the first clinically useful SERM, tamoxifen [1]. Rather than acting as a contraceptive, tamoxifen, then known as a nonsteroidal antiestrogen, was found to actually induce ovulation [2], an effect that led to the approval of tamoxifen and a related drug, clomiphene, for use as fertility agents [3–5]. Tamoxifen was later developed as a treatment for breast cancer, and it is currently approved for the treatment of all stages of breast cancer and for reducing the risk of breast cancer in high-risk women. While tamoxifen is a very effective breast cancer treatment due in part to its antiestrogenic effects in breast tissue, it was soon recognized that tamoxifen was having estrogenic effects in the endometrium, which is associated with an increased risk of endometrial cancer [6–9], on serum lipids [10, 11], and on bone [12, 13]. These observations led to efforts to develop new compounds, that is, SERMs, with the beneficial effects of estrogen on bone density and serum cholesterol [14–16] and without the negative side effects of tamoxifen and estradiol on the endometrium [6–9] and breast [17], respectively. Early SERM development was focused on breast cancer applications in an attempt to improve upon tamoxifen, but the success of raloxifene as an osteoporosis treatment [18], and the potential risks posed by long-term use of hormone replacement therapy (HRT) [17] in postmenopausal women, have generated an interest in developing new SERM compounds for the treatment of postmenopausal osteoporosis, menopausal symptoms,

sexual dysfunction, and for cardiovascular and cognitive benefits.

There are currently five major chemical classes of SERMs (see Table 1); however, only four SERMs have been approved for clinical use: tamoxifen, toremifene, clomiphene, and raloxifene. The "ideal" SERM would be a compound with beneficial estrogen-like effects on bone, the cardiovascular system, and cognition, while having antiestrogenic effects in the breast and endometrium. This compound would be devoid of side effects that impact a woman's quality of life, such as hot flashes and vaginal dryness, and life-threatening side effects, such as thromboembolic complications and breast or endometrial cancer [19]. None of the currently approved SERMs meet this definition, but several new agents are currently in development and will be discussed later in this chapter.

The need for an ideal SARM is also recognized since androgen replacement therapy employing steroidal androgens, for example, testosterone, in men is not without its drawbacks [20]. Testosterone, with the exception of testosterone undecanoate, has poor oral bioavailability due to extensive first-pass metabolism, and large variations in serum testosterone concentrations can be observed with intramuscularly injected testosterone preparations. Transdermal delivery of testosterone via scrotal and nonscrotal skin patches is also used, but these have been associated with localized skin irritation in up to 10% of patients using the nonscrotal patch [20]. The high doses of androgen used for hormonal male contraception can lead to weight gain, reductions in high-density lipoprotein (HDL) cholesterol, and acne [21]. Long-term effects on the prostate are another potential concern [22]. Thus, there is an interest in devel-

**Figure 2** Chemical Structures of Investigational SARMs.

oping orally bioavailable, nonsteroidal androgens that could provide the benefits of steroidal androgen therapy while avoiding steroid-related side effects. Compared to SERMs, the discovery of nonsteroidal androgens, now termed SARMs, was relatively recent, with the first such molecules being described in 1998 [23]. There are currently four major chemical classes of SARMs described in the medical literature (see Table 2). Although none of these new agents have been approved by the Food and Drug Administration (FDA), clinical trials are well underway.

Another factor driving the development of SARMs is our aging population. It is known that as men age, their serum testosterone levels gradually decline, potentially resulting in a condition known as androgen deficiency in the aging male (ADAM), also known as andropause [24]. Associated with the decline in serum testosterone is an increased estrogen-to-androgen concentration ratio in the prostate, which may factor in the development of benign prostatic hyperplasia (BPH) and potentially prostate cancer [25, 26]. Androgen deficiency can eventually lead to loss of libido, sexual dysfunction, and osteoporosis, among other symptoms, in older men [27]. The use of steroidal androgens in this population raises fears of increased prostate cancer risk, and therefore the potential risks of current treatment options must be weighed carefully. Thus, although the benefits of androgen replacement have long been known, more selective and efficacious treatment options, especially those with prostate-sparing effects, for example, SARMs, are clearly needed. Three excellent reviews [27–29] discuss the discovery and potential therapeutic applications of SARMs in more detail.

### 1.2 SERM and SARM Mechanisms of Action

Although the precise mechanisms of the tissue-selective actions of SERMs and SARMs remain incompletely understood, the principal effects of these agents are mediated via the ER and AR, respectively. Both the ER and AR are members of the nuclear receptor superfamily of ligand-activated transcription factors, which includes the progesterone, glucocorticoid, vitamin D, thyroid, and mineralocorticoid receptors. The ER and AR have a similar domain structure, with an amino-terminal domain containing the ligand-independent transactivation function 1 (AF-1), a centrally located deoxyribonucleic acid (DNA)-binding domain, and a carboxyl-terminal ligand-binding domain (LBD) containing a second, ligand-dependent transactivation function (AF-2). There are two known isoforms of the ER, designated α and β, while only one isoform of the AR has been observed. Upon binding their cognate ligands [estradiol for ER and testosterone or dihydrotestosterone (DHT) for AR], the receptors undergo a conformational change that dissociates them from heat shock proteins that stabilize them in an inactive conformation within the cytoplasm. The receptors then dimerize, translocate to the nucleus, and bind their respective DNA consensus sequences in the estrogen (ERE) and androgen response elements (ARE) within the promoter regions of estrogen- and androgen-regulated genes, respectively.

Whether a particular SERM or SARM acts as an agonist or antagonist is thought to depend on the specific conformational change of the receptor following binding of the ligands within the LBD, which is composed of 12 α-helices in both the ER and AR. The resulting position of helix 12 appears to be particularly important for transcriptional activation. When the ER and AR are bound to agonists such as estradiol or DHT, respectively, helix 12 folds to enclose the ligand within the LBD, allowing the receptor to interact with the coactivators and other elements of the general transcription machinery necessary for target gene expression [30–32]. If the receptors are bound to antagonists, helix 12 adopts a different, inhibitory conformation that promotes interaction with co-repressor proteins [33]. What is unique about the AR compared to the ER is that AF-1 appears to be the predominant transactivation function [34, 35]. In the ER, the ligand-dependent AF-2 is the predominant transactivation function [36]. The main function of AF-2 in the AR appears to be the promotion of an amino-terminal (N) to carboxyl-terminal (C) interaction (N/C interaction), which is dependent upon ligand binding [37, 38]. Whether this interaction is intramolecular or intermolecular is still a matter of debate; however, the most recent data suggests that the N/C interaction occurs intramolecularly [39]. There are conflicting data regarding the importance of the N/C interaction, with some studies showing that it is required for normal androgen target gene expression [40, 41], and other studies showing that AR target gene transcription can occur through AF-2 in the absence of an N/C interaction [42, 43]. Although the AR N/C interaction is known to decrease the ligand dissociation rate [44], a more recent study has shown that the N/C interaction may additionally play an important role in chromatin binding in vivo where remodeling of chromatin is necessary for target gene expression [41]. The N/C interaction is apparently not unique to the AR, as a similar type of interaction has been described for the ER [45].

## 2 CLINICAL TARGETS OF SERMS AND SARMS

There are numerous potential clinical targets for SERMs and SARMs in the genitourinary, musculoskeletal, and cardiovascular systems. Outlined in Table 3 are the primary clinical targets associated with these multifunctional agents. At present, there are four SERMs that have been FDA approved for clinical use: tamoxifen (for breast cancer treatment and prevention), toremifene (breast cancer treatment), raloxifene (treatment and prevention of postmenopausal osteoporosis), and clomiphene (induction of ovulation in anovulatory women). Although no SARMs have been approved for clinical use, the most mature of these agents have reached the phase II stage of clinical evaluation. Briefly discussed below are the current status of endocrine therapies, the current status of HRT, and the clinical use of tamoxifen, toremifene, and raloxifene.

**TABLE 3 Major Clinical Targets of Approved and Investigational SERMs and SARMs[a]**

| Clinical Target | SERM | SARM |
|---|---|---|
| Osteoporosis treatment | × | × |
| Osteoporosis prevention | × | × |
| Breast cancer treatment | × | |
| Breast cancer prevention | × | |
| Prostate cancer treatment | × | × |
| Prostate cancer prevention | × | × |
| Menopausal symptoms | × | |
| Urogenital atrophy | × | |
| Muscle wasting | | × |
| Male contraception | | × |
| BPH | | × |
| Hypogonadism/ADAM | | × |

[a]Currently, there are no drugs classified as SARMs that have been FDA approved for clinical use.

### 2.1 Current Status of Endocrine Therapy

Hormonal, or endocrine-based, therapies exist for a variety of maladies including prostate cancer (flutamide, nilutamide, and bicalutamide), breast cancer (tamoxifen, toremifene, and aromatase inhibitors), osteoporosis (raloxifene), menopausal symptoms (HRT), and androgen insufficiency or male hypogonadism (testosterone). Flutamide, nilutamide, and bicalutamide are nonsteroidal antiandrogens (not SARMs) used in androgen ablation therapy of prostate cancer [46]. As will be discussed below, the first SARMs were based on the structure of the nonsteroidal antiandrogens. For over 25 years, the triphenylethylene tamoxifen has been the endocrine treatment of choice for both early- and late-stage ER-positive breast cancer in postmenopausal women. In the last several years, however, third-generation aromatase inhibitors such as letrozole and anastrozole have proven to be more efficacious compared to tamoxifen in both advanced and early-stage breast cancer, which has led to aromatase inhibitors supplanting tamoxifen as the treatment of choice [47–50]. Aromatase inhibitors are currently being evaluated as potential breast cancer chemopreventive agents in postmenopausal women [50]. The triphenylethylene toremifene, a SERM related to tamoxifen, is approved for the treatment of metastatic breast cancer in postmenopausal women, and it is also currently being evaluated in a phase III clinical trial for prostate cancer chemoprevention [51]. The benzothiophene SERM raloxifene is currently approved for the treatment and prevention of postmenopausal osteoporosis. Raloxifene was also evaluated as a breast cancer chemopreventive agent in the recently completed Study of Tamoxifen and Raloxifene (STAR) [52]. Hormone replacement therapy (estrogen alone or estrogen plus progestin) is currently used for the alleviation of menopausal symptoms in postmenopausal women. Once thought to impart cardioprotective benefits in addition to its beneficial effects on bone mineral density (BMD) [16], the use of HRT is now largely restricted to short-term use for the alleviation of hot flashes due to the potential for life-threatening side effects associated with long-term use of HRT [17, 53]. Androgen insufficiency, also known as hypogonadism, ADAM, or andropause, is commonly treated with androgen supplementation (testosterone). As discussed earlier, this therapy is far from ideal [20–22], and it is hoped that a more efficacious therapy will result from current SARM development efforts.

### 2.2 Current Status of Hormone Replacement Therapy

The benefits of HRT in postmenopausal women include the prevention of osteoporosis [16] and the alleviation of menopausal symptoms [54, 55]. Prior to the Women's Health Initiative (WHI) study of HRT in healthy, postmenopausal women, it was also believed that HRT use was associated with cardiovascular benefits [56–58] and cognitive benefits such as the prevention of Alzheimer's disease [59–62], in addition to the positive effects of HRT on osteoporosis and menopausal symptoms. However, results from the WHI estrogen plus progestin study, a prospective, randomized, placebo-controlled clinical trial in 16,608 postmenopausal women without hysterectomy, have shown that HRT, given as 0.625 mg/day conjugated equine estrogens plus 2.5 mg/day of medroxyprogesterone acetate, provided no benefit in the primary prevention of coronary heart disease (CHD) and may actually increase the risk of CHD [17, 63]. Also, the incidence of invasive breast cancer, which was the primary adverse outcome measured in the trial, was found to be elevated in the HRT group [17]. Interestingly, in the WHI estrogen alone trial in hysterectomized postmenopausal women, a significant difference in breast cancer incidence was not observed between the estrogen and placebo groups, although an increased risk of stroke was seen [64, 65].

Furthermore, contrary to the earlier reported cognitive benefits of HRT, results from the WHI Memory Study (WHIMS) showed no improvement in cognitive function with HRT compared to placebo, and a small but significantly increased risk of cognitive decline in the HRT arm [66]. The risk of dementia was also significantly increased in postmenopausal women in the HRT group [67]. Similar declines in cognitive function and an increased risk of dementia were observed among those postmenopausal women who received estrogen alone in the WHIMS [68, 69]. In regard to the benefits of HRT in bone, the positive effects of HRT were confirmed in the WHI estrogen plus progestin study, with significant increases in BMD and a significantly reduced incidence of fractures in the HRT group [70]. Similar, positive bone effects were observed in the estrogen alone trial [64]. Ultimately, however, the increase in risks compared to benefits led to the early termination of both the WHI estrogen plus progestin trial and the estrogen alone trial [17, 64].

Although there has been some controversy surrounding the results from the WHI estrogen plus progestin trial because of the average age of the participants and the fact that it was stopped 3 years short of its planned 8.5 years [55, 58], the use of HRT declined following the announcement of the trial results [71]. Because of adverse effects, the long-term use of both HRT and unopposed estrogen is no longer recommended for the treatment or prevention of cardiovascular disease or the prevention of osteoporosis and dementia [72]. Consequently, there has been renewed

interest in SERMs that may potentially have many of the benefits of estrogen but with a lower incidence of its associated side effects.

### 2.3 Tamoxifen for Reducing the Risk of Breast Cancer

The benefits of using tamoxifen in the adjuvant setting for the treatment of postmenopausal ER-positive breast cancer, where it has been shown to significantly increase 10-year survival [73], led to the hypothesis that it may be useful for the primary prevention of breast cancer as well. Following the results of the National Surgical Adjuvant Breast and Bowel Project's (NSABP) Breast Cancer Prevention Trial (BCPT) [74], tamoxifen was approved for reducing the risk of breast cancer in women at high risk. Tamoxifen thus became the first agent, and first SERM, to demonstrate efficacy in the primary prevention of breast cancer in women at high risk. In that study, which included 13,388 women deemed to be at high risk of developing breast cancer, tamoxifen was shown to reduce the incidence of invasive and noninvasive breast cancers by 50% compared to placebo [74]. Two earlier studies failed to demonstrate this benefit, but they may have been confounded by the inclusion of hysterectomized women, who are at a lower risk for breast cancer, in one study [75, 76], and by a different basis of assessing risk in the other study [77]. These studies also had far fewer participants than the BCPT as well as variable use of HRT among the subjects [75–77]. The recently completed STAR trial, in which the efficacy of tamoxifen in preventing breast cancer was compared with that of raloxifene, showed that these two SERMs were equally efficacious in preventing invasive breast cancers, while the incidence of noninvasive breast cancers was higher in the raloxifene group [52]. However, because tamoxifen is also associated with an increased risk of endometrial carcinoma, thromboembolic complications, and vasomotor side effects [78], it is unlikely that tamoxifen will ever be used extensively as a breast cancer chemopreventive agent.

### 2.4 Raloxifene for Osteoporosis

Raloxifene is a benzothiophene derivative currently approved for the treatment and prevention of postmenopausal osteoporosis. Osteoporosis is a skeletal disease characterized by a progressive deterioration of the bone tissue resulting in an increased risk of fractures [79]. Following menopause, circulating estrogen levels decline, resulting in an imbalance between bone formation and bone resorption, which may lead to rapid bone loss and the development of osteoporosis [80, 81]. At one time known as keoxifene, raloxifene was originally developed as a breast cancer treatment, but after disappointing clinical trial results, raloxifene's development as a breast cancer agent was discontinued in the late 1980s [1]. However, the beneficial effects of SERMs on the maintenance of BMD [82], the possibility that they may not carry the increased risk of breast cancer associated with HRT, and clinical data showing the positive effects of raloxifene on BMD in postmenopausal women [18] led to the successful development of raloxifene as an osteoporosis drug. Furthermore, unlike tamoxifen, raloxifene lacks ER agonistic effects in the endometrium, and thus it has not been associated with an increased risk of endometrial cancer [18, 83]. Given its more favorable side effect profile compared to tamoxifen, and clinical trials data suggesting that it may be useful in breast cancer prevention [84, 85], raloxifene was compared to tamoxifen for efficacy in the primary prevention of breast cancer in the STAR trial [52].

### 2.5 Raloxifene for Reducing the Risk of Breast Cancer

Results from the Multiple Outcomes of Raloxifene Evaluation (MORE) trial, suggesting that raloxifene may be useful for breast cancer chemoprevention [85], and its more favorable side effect profile in regard to endometrial cancer risk [18, 83] led to the genesis of the NSABP P-2 trial, also known as the STAR trial. The STAR trial, a prospective, double-blind, randomized phase III trial comparing the effects of tamoxifen (20 mg/day) and raloxifene (60 mg/day) treatment on breast cancer incidence, was designed to measure the incidence of invasive and noninvasive breast cancer, uterine cancer, and thromboembolic events, among other endpoints, following 5 years of treatment with either raloxifene or tamoxifen in postmenopausal women at increased risk for breast cancer [52, 86, 87]. The results showed no significant difference between the raloxifene and tamoxifen treatment groups with respect to invasive breast cancer, with 168 and 163 cases observed, respectively [52]. For noninvasive breast cancer, however, the number of cases found in the raloxifene group (80) was higher than in the tamoxifen group (57), which was very close to being statistically significant [52]. These results would seem to indicate that raloxifene has little if any effect in preventing noninvasive breast cancer. Raloxifene was superior with respect to the incidence of uterine cancer, with 23 cases found in the raloxifene group compared to 36 cases in the tamoxifen group. This difference was, however, not significant [52]. The incidence of endometrial hyperplasia, on the other hand, was significantly lower in the

raloxifene group (14 cases) compared to the tamoxifen group (84 cases) [52]. When the incidence of thromboembolic events was considered, raloxifene also proved superior to tamoxifen, with 100 events observed in the raloxifene group and 141 events observed in the tamoxifen group [52].

### 2.6 Raloxifene for the Prevention of Cardiovascular Disease

Cardiovascular disease is the most common chronic disease in postmenopausal women in the United States, and it is the leading cause of death in American women. Raloxifene has been shown to reduce low-density lipoprotein (LDL) cholesterol and homocysteine levels in postmenopausal women, although levels of HDL cholesterol and triglycerides are not significantly affected by raloxifene treatment [88, 89]. Clinical data from women taking raloxifene for osteoporosis suggests that raloxifene may provide some cardiovascular benefits [90]. In order to determine whether raloxifene imparts any cardioprotective effects in postmenopausal women at risk of developing cardiovascular disease, the Raloxifene Use for the Heart (RUTH) trial was conducted [91]. The RUTH study was a double-blind, placebo-controlled clinical trial designed to determine the incidence of coronary events and breast cancer as primary outcomes [92]. The results showed that raloxifene (60 mg/day) had no significant effects on the risk of CHD compared to placebo. Moreover, raloxifene treatment was associated with a significantly increased risk of venous thromboembolic events and an increased risk of fatal stroke [91]. The RUTH trial did, however, confirm the benefit of raloxifene in preventing invasive breast cancer. Compared to placebo, raloxifene treatment (60 mg/day) resulted in a significant 44% reduction in the incidence of invasive breast cancer. As in the STAR trial, raloxifene had no significant effect on the incidence of noninvasive breast cancer [91].

Overall, raloxifene appears to be only marginally better than tamoxifen, and, as with tamoxifen, the risks associated with raloxifene treatment must be seriously considered before this drug is used in healthy women. Perhaps more importantly, the results of the STAR and RUTH trials pave the way for newer SERMs, with fewer associated side effects, in breast cancer prevention.

### 2.7 Toremifene for Breast Cancer

Toremifene is currently approved for the treatment of metastatic breast cancer in postmenopausal women. The pharmacological properties of toremifene are very similar to tamoxifen [93–96], which is not surprising considering that toremifene differs from tamoxifen by a single chlorine atom substitution. Multiple phase III trials have demonstrated that toremifene and tamoxifen have essentially equivalent efficacies and side effect profiles in the treatment of advanced breast cancer [97–101]. Two additional clinical trials have evaluated the efficacy of toremifene compared to tamoxifen in the adjuvant setting. As in advanced disease, there was no significant difference between toremifene and tamoxifen for adjuvant use in breast cancer [102, 103]. However, toremifene has not been approved for this indication in the United States. A notable finding in these adjuvant trials was that the incidence of secondary cancers was also similar [102, 103]. Although it has long been thought that toremifene has an advantage over tamoxifen in regard to the incidence of endometrial cancer because of its reduced genotoxic potential [104–106], it is still unclear whether toremifene offers any distinct benefit in this respect [107]. The most recent review of clinical data does, however, suggest that toremifene treatment may be associated with a lower incidence of endometrial carcinomas compared to tamoxifen [108]. In spite of its potential endometrial cancer benefit compared to tamoxifen, toremifene has many of the same side effects as tamoxifen [99] and is thus not being considered as a breast cancer chemopreventive.

### 2.8 Toremifene for the Prevention of Prostate Cancer

Following promising preclinical results seen with toremifene in the Transgenic Adenocarcinoma of Mouse Prostate (TRAMP) model [109], toremifene is currently being evaluated in clinical trials for prostate cancer chemoprevention. In a recently completed phase IIB study involving 514 patients with high-grade prostatic intraepithelial neoplasia (PIN), considered to be an indicator for the future development of prostate cancer, toremifene at a dose of 20 mg/day for 12 months was found to significantly reduce the incidence of prostate cancer compared to placebo [110]. In a previous exploratory phase IIA study in 21 men with high-grade PIN, 13 of the 18 subjects who completed toremifene treatment (60 mg/day for 4 months) were found to be free of high-grade PIN [111]. These promising results have led to the design of a phase III clinical trial of toremifene 20 mg/day compared to placebo for the prevention of prostate cancer in men with high-grade PIN. This trial is currently ongoing and involves 1260 men with high-grade PIN [112]. Toremifene has also been evaluated for efficacy in the treatment of prostate cancer in a phase II trial, but it was found to be ineffective [113]. As an agent for the prevention of prostate cancer, toremifene appears to be very promising.

## 3 AGENTS UNDER DEVELOPMENT AND THEIR POTENTIAL CLINICAL TARGETS

Discussed below are five different investigational SERMs (ospemifene, arzoxifene, bazedoxifene, acolbifene, and lasofoxifene) and SARMs (S-1, S-4, BMS-564929, LGD-2226, and S-40503) and their potential clinical targets.

### 3.1 SERMs

***Ospemifene*** Ospemifene is a triphenylethylene similar in structure to toremifene (Fig. 1). Originally developed as an osteoporosis agent [114, 115], ospemifene has now completed phase III clinical evaluation for the treatment of vulvovaginal atrophy (VVA) due to its estrogenic effects in the vaginal epithelium [116–119], a property that appears to be unique to ospemifene among the current investigational and approved SERMs. In preclinical animal models, ospemifene has also been shown to have breast cancer chemopreventive effects [114, 120, 195]. Phase I studies have indicated that ospemifene is generally safe and well tolerated, with pharmacokinetics suitable for once-a-day dosing [116, 121]. One of the main concerns with investigational SERMs is their potential for estrogenic activity in the uterus. Tamoxifen's estrogenic effect on the endometrium and its association with endometrial cancer are well known, and, in order to be successful, any new SERM must be largely devoid of endometrial side effects. The effects of ospemifene on the uterus have been studied both preclinically and clinically, and the data show that ospemifene has neutral to slight, yet insignificant, estrogen agonist activity in the uterus [114, 116–119, 196], comparable to raloxifene [118].

*Ospemifene for the Treatment of Vulvovaginal Atrophy* Perhaps the most interesting observation from the early clinical studies of ospemifene is that it has a strong estrogenic effect on the vaginal epithelium [116–119], an effect that has not been observed with other SERMs, with the possible exception of lasofoxifene [122]. Raloxifene does not have this effect and may in fact aggravate the condition [123]. Thus, ospemifene may be a novel treatment for urogenital atrophy, also known as vulvovaginal atrophy (VVA), a condition that affects approximately 40% of postmenopausal women [124]. In a placebo-controlled phase II study, the effects of ospemifene (30, 60, and 90 mg/day for 12 weeks) on the vaginal epithelium were assessed using Pap smears. Specifically, the percentages of cells in the parabasal, intermediate, and superficial layers were determined and the changes were compared to placebo. Significant changes were seen at all dose levels for all cell types compared to placebo, except for superficial cells at the 30-mg dose level [117]. Similar effects were observed in another phase II study as well as in a repeated-dose phase I study [116, 118]. Ospemifene has been evaluated in three phase III clinical trials for efficacy in treating VVA, the symptoms of which include vaginal dryness, dyspareunia, and incontinence in postmenopausal women [197]. The first randomized, double-blind phase III trial included 826 postmenopausal women who were randomly assigned to receive either placebo or ospemifene at 30 or 60 mg/day for 12 weeks [196, 198, 199]. All of the subjects in this trial had at least one moderate or severe symptom of VVA in addition to having a vaginal pH greater than 5.0 and less than 5% superficial cells in the vaginal smear. Efficacy of treatment was assessed by measuring four co-primary endpoints: changes from baseline to week 12 in the percentages of superficial and parabasal cells in the vaginal smear (vaginal maturation index), vaginal pH, and self-assessed most bothersome symptom (MBS) of vaginal dryness or dyspareunia compared to placebo. Except for dyspareunia at the 30-mg dose, both doses of ospemifene showed statistically significant improvements from baseline to week 12 in all four co-primary endpoints compared to placebo, with the 60-mg dose being more efficacious than the 30-mg dose. Ospemifene was well tolerated, with no significant differences in adverse events between the treatment groups. Only minor, clinically insignificant changes were seen in endometrial thickness with ospemifene treatment [196], as seen in phase II [117].

These positive results were reinforced in the second randomized, double-blind, placebo-controlled phase III clinical trial in 919 postmenopausal women suffering from VVA. Based on their MBS of either vaginal dryness or dyspareunia, these women were stratified into two cohorts [198]. This trial compared ospemifene 60 mg/day for 12 weeks to placebo. The same co-primary endpoints as in the first phase III trial were used in this trial. In the cohort including 314 women reporting vaginal dryness as their MBS, highly significant changes were seen from baseline to week 12 compared to placebo for percentages of superficial and parabasal cells in the vaginal maturation index as well as vaginal pH. Ospemifene also significantly improved the MBS of vaginal dryness. In the second cohort of 605 women identifying dyspareunia as their MBS, very highly significant changes from baseline to week 12 were observed for all four co-primary endpoints compared to placebo [198]. The phase III long-term safety study showed that the positive effects of ospemifene are maintained over a one-year period. This study included 118 women who continued from the second phase III study of ospemifene 60 mg/day versus placebo [198].

The phase III clinical data clearly show that ospemifene is a safe and effective treatment for VVA, and now that the phase III development program for ospemifene has been completed, a New Drug Application (NDA) is expected to be filed with the FDA by the end of 2012.

*Ospemifene for Osteoporosis Prevention and Treatment* Results from preclinical studies [114, 125] and two phase II clinical trials have shown that ospemifene has potential for use in the treatment and prevention of osteoporosis. The first phase II study compared ospemifene at 30, 60, and 90 mg/day to raloxifene 60 mg/day for 12 weeks in postmenopausal women. Levels of biochemical markers of bone resorption (urinary outputs of N- and C-terminal cross-linking telopeptides of type I collagen, NTX and CTX, respectively) and formation [serum osteocalcin, bone-specific alkaline phosphatase (ALP), and procollagen type I N and C propeptide, PINP and PICP, respectively] following ospemifene treatment were comparable to the levels seen following raloxifene treatment, which demonstrates that the bone-sparing effects of ospemifene are equivalent to those of raloxifene [126]. Only minor changes in endometrial thickness were observed in all study groups, and no significant differences in endometrial thickness were seen between groups [118]. In the second phase II study, ospemifene treatment at 30, 60, and 90 mg/day for 3 months was compared to placebo in healthy postmenopausal women [115]. Urinary concentrations of NTX and CTX and serum levels of PINP, PICP, and ALP were measured to assess bone resorption and formation, respectively. A significant, dose-dependent decrease was seen in the levels of NTX at all dose levels compared to placebo, and CTX was significantly decreased at the 90-mg dose level. Levels of PINP, PICP, and bone ALP were significantly decreased at the 60- and 90-mg ospemifene dose levels compared to placebo [115]. Furthermore, ospemifene was not associated with endometrial stimulation, nor did it worsen climacteric symptoms [117].

Together, the preclinical and clinical data on ospemifene's effects in bone indicate that it is effective in reducing bone turnover, similar to raloxifene. However, it should be emphasized that the clinical trial study periods were only 12 weeks, and longer-term studies in more subjects are needed to fully assess the potential of ospemifene to prevent and treat osteoporosis.

*Ospemifene for Breast Cancer Prevention* In vitro and in vivo preclinical data suggest that ospemifene may potentially help prevent the development of breast cancer. In a rat model of dimethylbenzanthracene (DMBA)-induced mammary carcinoma, treatment with ospemifene reduced the incidence of mammary tumors dose dependently [114]. In nude mice bearing MCF-7 human breast cancer xenografts, ospemifene treatment following estrogen withdrawal did not support tumor growth or the expression of pS2 [114]. Ospemifene was also shown to inhibit the growth of MCF-7 xenografts in nude mice compared to control, indicating that ospemifene acts as an antagonist in breast tissue [127]. In a mouse model of DMBA-induced mammary carcinoma, ospemifene was shown to significantly reduce the incidence of breast tumors, similar to tamoxifen, in separate 37- and 52-week studies [120]. Most recently, ospemifene was shown to both prevent and treat breast cancer in an immune-intact transgenic mouse model of spontaneous breast cancer [195]. Although these preclinical results look promising, clinical trials are needed to assess the breast cancer chemopreventive and therapeutic potentials of ospemifene in humans.

***Arzoxifene*** A benzothiophene related to raloxifene, arzoxifene (Fig. 1) has been developed primarily for the prevention and treatment of breast cancer, while also having been studied for efficacy in preventing osteoporosis and the treatment of endometrial cancer. Arzoxifene, currently in phase III development, was first described in 1997 as a new SERM more potent than raloxifene in antagonizing the effects of estradiol in breast and uterine tissue, as well as having bone-sparing and cholesterol-lowering effects in ovariectomized rats [128].

*Arzoxifene for Breast Cancer Prevention and Treatment* In preclinical studies, arzoxifene has been shown to be effective in the treatment and prevention of breast cancer [129–134]. Clinical trials of arzoxifene in breast cancer that have been completed and published thus far include three phase I and two phase II studies [135–138]. In a phase I study of arzoxifene in 32 patients with recurrent or metastatic breast cancer, subjects received 10, 20, 50, or 100 mg/day arzoxifene. Although no clinical responses were observed, six patients had their disease stabilized for a median duration of 7.7 months. Following 12 weeks of therapy, no evidence of endometrial thickening was found. Overall, the treatment was well tolerated, with mild to moderate hot flashes being the most frequently encountered side effect. Given that all study subjects had previously failed tamoxifen therapy, the lack of responses in this trial was not surprising [135].

Two additional phase I trials were conducted to determine whether arzoxifene has any potential as a breast cancer chemopreventive agent. The first study, a phase IA, included 50 pre- or postmenopausal women randomized to receive no treatment or 10, 20, or 50 mg/day arzoxifene. The other study, a phase IB, included 76 postmenopausal women randomized to receive either

placebo or 20 mg/day arzoxifene. In both trials, sex hormone binding globulin levels were increased, insulin-like growth factor 1 (IGF-1) levels decreased, and the ratio of IGF-1 to IGF binding protein 3 was significantly decreased compared to placebo in the phase IB. Decreases in biomarkers of proliferation were more prevalent for arzoxifene 20 mg in the phase IA study, and in the phase IB study, ER expression was significantly decreased by arzoxifene, although changes in proliferation biomarkers were not significantly different from placebo. The most common side effects were hot flashes, headaches, nausea, leg cramps, and breast pain; however, none of these were significantly increased by arzoxifene compared to placebo in the phase IB study [136]. Further study is needed to determine whether arzoxifene could potentially be useful for breast cancer chemoprevention.

The efficacy of arzoxifene in treating locally advanced or metastatic breast cancer was examined in two phase II studies, the first of which included 112 women receiving either 20 or 50 mg/day arzoxifene. Forty-nine of these patients were considered tamoxifen sensitive and 63 were tamoxifen refractory. Interestingly, the response rate among tamoxifen-sensitive patients receiving 20 mg arzoxifene was more than triple that seen at 50 mg (26.1 vs. 8.0%). Time to progression was also more than double at the lower dose. In tamoxifen-refractory patients, no differences in response rate or time to progression were noted between the two doses. The most common side effects were hot flashes, nausea, cutaneous toxicity, neuromotor toxicity, weight changes, alopecia, headache, and vomiting [137]. The other phase II study involved 92 patients given either 20 or 50 mg/day arzoxifene for 12 weeks. The results of this trial were very similar to the first trial; however, a response rate of 42.9% was observed at the 20-mg dose level compared to 27.3% at the 50-mg dose [138].

In a phase III trial of arzoxifene compared to tamoxifen as first-line therapy for breast cancer, women with ER-positive breast cancer were randomized to receive either 20 mg tamoxifen or 20 mg arzoxifene. During the first interim analysis, time to progression was determined and arzoxifene was found to be inferior to tamoxifen, which led to this trial being halted early [139]. The future of arzoxifene in cancer is now uncertain.

*Arzoxifene for the Prevention of Osteoporosis* Arzoxifene's effects on preventing bone loss have been studied in ovariectomized (OVX) rats [128, 140–142]. In a 5-week study in OVX rats administered 0.1 μg–10 mg/kg/day arzoxifene, OVX-induced bone loss was significantly prevented by arzoxifene, with maximal effects observed at the 0.1- to 1.0-mg/kg dose level. Arzoxifene also maintained bone strength in the femoral neck and midshaft. Compared to OVX control, arzoxifene had only slight estrogenic effects on uterine weight, similar to raloxifene; however, no stimulatory effect on the endometrium was observed. The efficacy of arzoxifene in this study was found to be equivalent to both estradiol and raloxifene; however, arzoxifene was more potent than raloxifene [141]. When administered long term (one year), similar effects were observed with arzoxifene dosed orally at 0.1 or 0.5 mg/kg/day in OVX rats. Arzoxifene prevented OVX-induced increases in body weight, serum cholesterol, and prevented bone loss associated with OVX. No significant uterine histological changes were seen, and arzoxifene had only a slight estrogenic effect on uterine weight compared to OVX controls [142]. Although these preclinical data appear promising, no clinical data regarding the effects of arzoxifene on bone health have been published. There are, however, phase III studies of arzoxifene underway that should help determine the potential of arzoxifene in postmenopausal osteoporosis [139].

***Bazedoxifene*** An indole derivative that structurally resembles raloxifene, bazedoxifene (Fig. 1) is currently in phase III clinical trials for osteoporosis treatment and prevention, as well as treatment of menopausal symptoms (in combination with conjugated estrogens). Although phase I–II trials of bazedoxifene have been completed, few clinical data have been published. A review summarizing this data was published in 2004 [143]. Published results of pertinent preclinical studies will be discussed, followed by an overview of the available clinical trials data.

*Bazedoxifene for Osteoporosis Prevention and Treatment* The potential of bazedoxifene to prevent bone loss was evaluated using the OVX rat model. Bazedoxifene was administered orally at doses ranging from 0.1 to 3.0 mg/kg/day for 6 weeks. Starting at 0.3 mg/kg, bazedoxifene significantly prevented the loss of BMD in the proximal tibia compared to OVX control. At the lowest dose, 0.1 mg/kg, bazedoxifene reduced total serum cholesterol by 50% compared to OVX control, while uterine wet weight was not significantly affected in any dose group [144]. Similar results were seen in a newer study [145]. When evaluated in immature rats with 3 days of treatment, bazedoxifene at doses of 10 or 100 μg had no significant effects on uterine wet weight and completely antagonized the stimulatory effects of estradiol [144]. In another study in the immature rat model, bazedoxifene produced a small increase in uterine wet weight at 0.5 mg/kg and had no significant effects at 5.0 mg/kg. Interestingly, bazedoxifene antagonized the uterine stimulatory effects of raloxifene in this study [145].

In a phase II trial in 494 healthy postmenopausal women, bazedoxifene was dosed at 5, 10, or 20 mg/day for 90 days in combination with a 600-mg/day calcium supplement. Markers of bone turnover were reduced dose dependently compared to placebo, with statistical significance already observed at 5 mg/day [143]. Similarly suggestive results were observed in a previous phase I study in 107 healthy postmenopausal women. In that study, bazedoxifene was administered orally for 30 days at doses of 1–80 mg/day. Urinary concentrations of NTX were reduced by approximately 20%, with no significant adverse effects [143]. Bazedoxifene's efficacy in the treatment and prevention of osteoporosis is currently being examined in two phase III clinical trials [143, 146].

*Bazedoxifene for the Treatment of Menopausal Symptoms* Preclinically, the effects of bazedoxifene on the relief of menopausal symptoms were assessed using the rat hot flash model. When mature, OVX rats that have developed a morphine dependency are given the opioid antagonist naloxone, an intense vasomotor response can be detected in the tail, where a 4–5°C increase in temperature can be observed within 30 minutes of injection. This response can be inhibited by estradiol. Bazedoxifene antagonized estradiol's effects at doses above 1.0 mg/kg, but not at the effective bone-sparing dose of bazedoxifene (0.3 mg/kg). Thus, bazedoxifene, but not raloxifene, could be given in combination with estrogen to treat osteoporosis without antagonizing estrogen's effects on hot flash alleviation. Bazedoxifene would, however, antagonize the effects of estradiol in the breast and endometrium [145, 147].

In a phase II trial of 10 and 20 mg bazedoxifene in combination with conjugated estrogens, bazedoxifene significantly inhibited the stimulatory effects of the conjugated estrogens on the endometrium at both doses compared to conjugated estrogens alone. Menopausal symptoms were also significantly reduced with the combination compared to placebo [143]. The uterine safety and the efficacy of bazedoxifene in treating menopausal symptoms are currently being examined in a phase III clinical trial of bazedoxifene in combination with conjugated estrogens versus HRT [143]. An additional phase III trial testing bazedoxifene plus conjugated estrogens versus raloxifene for uterine safety is also under way [143]. In regard to uterine safety, results from a 6-month study of bazedoxifene in 497 healthy postmenopausal women revealed no significant changes in endometrial thickness at doses of 2.5–20 mg/day compared to placebo; however, significant decreases in endometrial thickness were observed at the 30- and 40-mg doses. This finding is notable because uterine antagonism has not previously been reported for any of the other SERMs [148].

***Acolbifene*** Acolbifene (Fig. 1) is a benzopyran derivative currently in phase II development for the treatment of breast cancer [149]. This compound is the active metabolite of the precursor molecule EM-800, and among the currently known SERMs, it is the most potent antiestrogen [150]. Numerous preclinical studies have examined the effects of acolbifene and its precursor in preventing bone loss as well as preventing and treating breast cancer. Based on the results of the only currently published clinical trial of acolbifene, the intended target for this new SERM appears to be breast cancer treatment. A summary of the preclinical data and a discussion of the phase II trial results follow.

*Acolbifene for the Treatment and Prevention of Breast Cancer* Preclinically, the potential of acolbifene to prevent and treat breast cancer was studied in the rat model of DMBA-induced mammary carcinoma [151] and in a mouse breast cancer xenograft model [152]. In the prevention study, rats were dosed orally with vehicle control, or 25, 75, or 250 μg/day acolbifene for 9 months. Mammary tumor incidence in all dose groups was significantly reduced compared to control, although tumor incidence was still 28% at the highest dose, compared to an incidence of 95% in the control. Total serum cholesterol, triglycerides, and uterine wet weight were significantly reduced at all doses, while no significant effects were observed on bone mineral content or BMD [151]. When acolbifene (500 μg/day for 287 days) was orally administered to OVX nude mice bearing ZR-75-1 human breast tumor xenografts, the tumors regressed to 20% of pretreatment size and became undetectable in 65% of the treated mice. Interestingly, 93% of the tumors that became undetectable did not recur upon treatment with estradiol for 12 weeks [152].

In a phase II clinical trial in 43 women with tamoxifen-refractory breast cancer, acolbifene, in the form of the EM-800 prodrug, was administered orally at 20 or 40 mg/day for 6 months. An objective response rate of approximately 12% was observed, slightly better than that observed with arzoxifene [138] in this patient population [149]. Stabilization of disease was observed in 10 patients for at least 3 months and in 7 patients for at least 6 months. Median response duration was approximately 8 months. Overall, the treatment was well tolerated, and the most frequently encountered side effects included bone/muscle pain, nausea, fatigue, vomiting, headache, and diarrhea [149, 153]. This study demonstrated that acolbifene is incompletely cross-resistant with tamoxifen and may potentially be of some value for salvage therapy in patients that have failed on tamoxifen. A phase III trial of acolbifene versus the aromatase inhibitor anastrozole in patients who had

failed to respond to tamoxifen was conducted, but acolbifene proved to be far less efficacious than anastrozole, leading to early termination of the trial [154].

*Acolbifene for the Prevention of Osteoporosis* The effects of acolbifene on BMD have been evaluated in the OVX rat model [155–157]. Goss et al. [155] looked at the effects of acolbifene (0.01, 1.0, and 2.5 mg/kg/day for 12 weeks) alone and in combination with estradiol on bone, serum lipids, and the uterus. Compared to OVX controls, femoral and lumbar vertebral BMD was significantly higher in the treated groups after 12 weeks of treatment. Furthermore, the combination of estradiol and acolbifene resulted in higher BMD levels than estradiol treatment alone. Acolbifene treatment was also associated with a significant reduction in the OVX-induced increase in serum markers of bone turnover, and mechanical bone strength was increased. At the two higher dose levels, acolbifene antagonized the stimulatory effects of estradiol on the endometrium, while showing no stimulatory effects as a single agent [155]. A similar study showed that acolbifene, given in combination with estradiol, blocked estradiol's stimulation of uterine and breast tissue, while still maintaining BMD [156]. Thus, the potential exists for acolbifene to be used in combination with estradiol, similar to bazedoxifene. In a study by Martel et al. [157], the effects of acolbifene and raloxifene on the prevention of bone loss in OVX rats were compared. Acolbifene and raloxifene were administered orally at doses of 0.01–1.0 mg/kg/day for 37 weeks. Lumbar spine and femoral BMD were maintained at 90–93% and 85–90% of intact control by acolbifene and raloxifene, respectively. At the lowest dose, acolbifene significantly maintained trabecular bone volume, while raloxifene had no discernable effect. At the highest dose, the two SERMs were equivalent. With respect to endometrial effects, raloxifene, but not acolbifene, was associated with hypertrophy of the uterine endometrium at the highest dose [157]. This study demonstrated that acolbifene is more potent than raloxifene without having stimulatory effects on the endometrium.

The most recent preclinical data suggests that acolbifene also has potential as a cholesterol-lowering agent [158] as well as a treatment for vaginal atrophy in combination with conjugated estrogens and dehydroepiandrosterone [159]. Overall, acolbifene appears to be a very promising new SERM; however, very little clinical data exist for this compound, and thus no firm conclusions can be drawn regarding its clinical potential. One potentially troubling finding is that reactive metabolites of acolbifene have been shown to form DNA adducts and produce DNA damage [160]. The significance of this finding is unknown.

***Lasofoxifene*** Lasofoxifene is another interesting new SERM that has reached phase III development. Like nafoxidine, lasofoxifene (Fig. 1) is a naphthalene derivative; however, lasofoxifene is not a planar molecule, a property that gives it a high degree of potency and much better oral bioavailability than raloxifene [161]. Pharmacokinetic data from phase I studies show that lasofoxifene has a very long terminal half-life of elimination ranging from 165 to 193 h in healthy subjects [162, 163]. Lasofoxifene has been developed primarily for the treatment and prevention of osteoporosis [164, 165]. Preclinical data show that lasofoxifene also has potential utility in the treatment and prevention of breast cancer [166] and vaginal atrophy [122].

*Lasofoxifene for the Treatment and Prevention of Breast Cancer* The potential for lasofoxifene to prevent and treat breast cancer has been studied in the rat model of *N*-nitroso-*N*-methylurea-induced mammary carcinoma [166]. For breast cancer treatment, tamoxifen or lasofoxifene was orally administered to groups of 12 induced rats at doses of 0.1–10 mg/kg/day. Treatments began upon the appearance of the first control tumor with a diameter >1 cm and continued for up to 20 weeks postinduction. Compared to control, lasofoxifene significantly inhibited tumor growth, similar to tamoxifen. For breast cancer prevention, groups of 20 induced rats were treated with tamoxifen (10 mg/kg) or lasofoxifene (0.1–10 mg/kg) starting at 2 weeks postinduction and continuing for 8 weeks. Treatments were then stopped and the rats monitored for 8 additional weeks. At the highest dose level, lasofoxifene significantly increased tumor latency and significantly decreased tumor incidence to 30%, compared to 75% in the control. Tamoxifen at the same dose level decreased tumor incidence to 15% [166]. These preliminary data look promising, but more studies are needed to determine the potential of lasofoxifene to prevent or treat breast cancer.

*Lasofoxifene for the Treatment and Prevention of Osteoporosis* Numerous preclinical studies looking at the ability of lasofoxifene to prevent osteoporosis in rats and monkeys have been performed [122, 161, 166–170]. These studies indicate that lasofoxifene effectively and potently prevents bone loss and reduces bone turnover in OVX rats, and in orchidectomized (ORX) and aged male rats, lasofoxifene has shown an ability to prevent bone loss without affecting the prostate [168, 169]. In OVX cynomolgus monkeys, lasofoxifene (1.0 and 5.0 mg/kg) prevented the loss of BMD and inhibited bone turnover over a 2-year period [170].

Clinically, lasofoxifene has been evaluated in several phase II and phase III clinical trials [165]. In a 2-year phase II study, 410 postmenopausal women were ran-

domized to receive placebo, 0.25 mg/day lasofoxifene, 1.0 mg/day lasofoxifene, or 60 mg/day raloxifene. Changes in lumbar spine and total hip BMD were assessed. Lasofoxifene treatment was associated with significant increases in lumbar spine BMD at both doses compared to placebo and to raloxifene. Lasofoxifene and raloxifene had similar effects on total hip BMD. With respect to biochemical markers of bone turnover, both raloxifene and lasofoxifene treatment produced significant reductions compared to placebo, with the reductions following lasofoxifene treatment generally greater than those seen following raloxifene treatment. While the adverse events seen with lasofoxifene and raloxifene were generally similar, there was one important difference. Both doses of lasofoxifene were associated with significant increases in endometrial thickness compared to placebo, while raloxifene did not significantly affect the endometrium [171]. Other phase II studies of lasofoxifene have also demonstrated the positive, bone-sparing effects of this novel SERM [165]. Preliminary results from a completed 2-year phase III trial in 1,907 healthy postmenopausal women show significant increases in lumbar spine and femoral BMD at all dose levels of lasofoxifene (0.025, 0.25, and 0.5 mg/day) compared to placebo. The most frequently reported adverse events were hot flashes and leg cramps [165]. Two additional phase III trials of lasofoxifene are still ongoing, one assessing the efficacy of lasofoxifene in reducing spinal fractures and another comparing the efficacy of lasofoxifene to raloxifene [165].

As alluded to above, lasofoxifene may have beneficial, estrogen-like effects on the vaginal epithelium, similar to ospemifene. In a long-term study of lasofoxifene in rats, all lasofoxifene-treated animals that were examined had vaginal mucification, compared to about 46% of OVX controls that showed vaginal atrophy [122]. In a phase II study, lasofoxifene, dosed at 0.025, 0.25, and 0.5 mg/day, was associated with significant declines in vaginal pH and parabasal cells and a significant increase in superficial cells compared to placebo following 3 months of treatment at all dose levels [165]. Similar improvements in the same measures of vaginal atrophy were observed in a phase III trial following 1 and 2 years of treatment with lasofoxifene at the same doses [165]. Results from a short-term study using immature OVX rats suggest that increased levels of ERβ and AR may be the mechanism through which lasofoxifene exerts its effects on the vaginal epithelium [172]. Finally, in what could be a potential safety concern, lasofoxifene was reported to stimulate uterine matrix metalloprotease 2 activity in rats to the same degree as estradiol [173].

Although lasofoxifene appears to be a very promising new SERM, the manufacturer received a nonapprovable letter from the FDA in late 2005 following submission of a new drug application seeking approval for lasofoxifene as a treatment for osteoporosis. The future of this compound is thus uncertain.

### 3.2 SARMs

***3-(4-Fluorophenoxy)-2-Hydroxy-2-Methyl-N-[4-Nitro-3-(Trifluoromethyl)Phenyl]-Propanamide (S-1)*** This compound (Fig. 2), referred to in the literature as S-1, is an aryl propionamide derivative, a chemical class of SARMs based on the structure of the antiandrogen bicalutamide. The aryl propionamide SARMs were the first to be described [23]. S-1 is currently in phase I clinical development [28], but no clinical data are available in the literature. In a preclinical study, the tissue-selective pharmacological activity of S-1 was demonstrated using castrated rats. Following 14 days of treatment with S-1 at 0.1–1.0 mg/day, only minor stimulation of the prostate and seminal vesicles was observed compared to castrated controls, but the weight of the levator ani muscle was restored to approximately 74% of intact control. These data show that the activity of this compound is selective for anabolic organs compared to androgenic organs [174]. Pharmacokinetic studies of S-1 in rats at doses ranging from 0.1 to 30 mg/kg show that this compound is rapidly absorbed, and it has an oral bioavailability of approximately 55–60%. S-1 is extensively metabolized and eliminated both in the urine and feces, with a terminal half-life of 3.6–5.2 h [175]. Preclinical data indicate that this compound may potentially be useful in the treatment of BPH [176].

*S-1 and the Treatment of BPH* As a follow-up to the earlier study where S-1 was shown to selectively maintain levator ani muscle mass in castrated male rats without substantially affecting the prostate [174], the effects of S-1 compared to finasteride, a 5α-reductase inhibitor, and hydroxyflutamide, an antiandrogen, were determined in intact male rats to assess the potential of S-1 as a treatment for BPH [176]. Benign prostatic hyperplasia is a common ailment in men over the age of 50, and it is characterized by an enlarged prostate gland, which leads to difficulty in urination [177]. Intact male rats were dosed with S-1 (5, 10, and 25 mg/kg), hydroxyflutamide (0.5, 1, 5, 10, and 25 mg/kg), or finasteride (5 mg/kg) for 9 days. All three compounds caused significant reductions in prostate weight, but only hydroxyflutamide caused a significant decrease in levator ani muscle mass. Hydroxyflutamide treatment also resulted in dose-dependent increases in serum testosterone, luteinizing hormone (LH), and follicle stimulating hormone (FSH) levels, while S-1 did not increase the serum hormone levels. Finasteride, due to

its inhibition of 5α-reductase, caused a significant increase in testosterone levels by 9 days of treatment [176]. This study further demonstrated the tissue-selective effects of S-1 and its potential to be used as a treatment for BPH.

***S-3-(4-Acetylaminophenoxy)-2-Hydroxy-2-Methyl-N-(4-Nitro-3-Trifluoromethylphenyl)-Propionamide (S-4)*** Another aryl propionamide SARM referred to in the literature as S-4 (Fig. 2) is also currently in phase I clinical development [28], although published clinical data are lacking. The synthesis of this compound was described in 2004 [178]. Pharmacokinetic studies in rats using orally (1, 10, and 30 mg/kg) and intravenously (0.5, 1, 10, and 30 mg/kg) administered doses of S-4 revealed that the oral bioavailability of S-4 is essentially complete at the lower doses, and S-4's terminal half-life of elimination is very similar to that of the S-1 sister molecule (2.6–5.3 h) [179]. In vitro metabolism studies showed that deacetylation catalyzed by cytochrome P450 3A4 is the major phase I reaction [180]. Like S-1, S-4 was shown to have tissue-selective anabolic effects in castrated and intact male rats; however, the effects of S-4 on the levator ani muscle were greater than the effects of both S-1 and testosterone [174, 176], suggesting that S-4 may be useful in treating muscle wasting. The most recent preclinical data show that S-4 could potentially be useful in preventing and/or treating osteoporosis in both men and women [181, 182].

*S-4 for the Prevention of Osteoporosis* The abilities of S-4 and DHT to restore ORX-induced bone loss were compared in a 20-week study in ORX male rats. Twelve weeks after being orchidectomized, the rats were treated with S-4 (3 and 10 mg/kg), DHT (3 mg/kg), or vehicle control for 8 weeks. A group of intact, vehicle-treated control rats was included. Serum osteocalcin levels in the S-4 and DHT-treated ORX rats were significantly lower compared to the intact controls, suggesting reduced bone turnover. Compared to the ORX controls, treatment with S-4 increased total body BMD significantly more than DHT. The 10-mg/kg dose of S-4 also produced a significant increase in total body bone mineral content (BMC) compared to ORX controls. In contrast, no significant changes in either BMD or BMC were observed with DHT treatment [181].

In the same study, the effects of S-4 treatment on the soleus and levator ani muscles, the prostate and seminal vesicles, and plasma gonadotropin levels were assessed. Interestingly, soleus muscle mass was not significantly different in the S-4 and DHT-treated rats compared to the ORX controls after 8 weeks of treatment. Soleus muscle strength, however, was significantly increased by S-4 and DHT. As in previous studies, levator ani muscle mass was increased by S-4 to intact control levels. Although their anabolic effects were similar, the effects of S-4 and DHT on the prostate and seminal vesicles were strikingly different. Dihydrotestosterone treatment caused the prostate and seminal vesicle weights to increase to more than 200% of the weights observed in the intact controls, while treatment with S-4 at 3 mg/kg had only minimal effects on the weights of these organs (16 and 17% of intact control, respectively). Both doses of S-4 produced significant decreases in plasma LH and FSH compared to ORX control, suggesting agonist action in the pituitary; however; LH and FSH levels were still significantly higher in the S-4 3-mg/kg group compared to intact controls. Treatment with DHT reduced LH and FSH to intact control levels, as expected [181].

The bone-sparing effects of S-4 have also been shown in a female rat model of osteoporosis. One day after ovariectomy, rats were administered S-4 at doses ranging from 0.1 to 3.0 mg/day by subcutaneous injection. After approximately 4 months of treatment, whole-body BMD, L5–L6 vertebral BMD, cortical and trabecular BMD, and femoral bone strength were assessed. At S-4 doses >0.1 mg/day, whole-body BMD was significantly greater than OVX control. At the 3-mg/day dose, S-4 fully preserved whole-body BMD. The coadministration of bicalutamide partially antagonized the effects of S-4, suggesting that S-4's effects were mediated through the AR. Vertebral L5–L6 BMD in OVX rats increased dose dependently with S-4 treatment. At the highest S-4 dose (3 mg/day), vertebral BMD was fully maintained. Treatment with DHT failed to prevent bone loss in the L5–L6 region. Again, coadministration of bicalutamide partially opposed the bone-sparing effects of S-4 alone. In cortical bone, the two highest doses of S-4 (1.0 and 3.0 mg/day) fully maintained cortical BMC and BMD at the femoral midshaft, while DHT only partially prevented bone loss in this region. With respect to trabecular BMD in the distal femur, S-4 only partially prevented the loss of bone in OVX animals. In S-4-treated intact rats, however, trabecular BMD was significantly increased compared to vehicle-treated intact rats. Finally, femoral bone strength was fully maintained by S-4, similar to DHT [182]. This was the first study to demonstrate the bone-sparing effects of a SARM in a rat model of postmenopausal osteoporosis.

***(7R,7aS)-2-(3-Chloro-4-Cyano-2-Methylphenyl)-7-Hydroxytetrahydro-2H-Pyrrolo[1,2-e]Imidazole-1,3-Dione (BMS-564929)*** BMS-564929 (Fig. 2) is a bicyclic hydantoin derivative, a chemical class of SARMs based on the structure of the antiandrogen nilutamide

[27]. Based on the latest published data, this potent, muscle-selective compound appears to be targeted toward the treatment of age-related musculoskeletal decline, or muscle wasting [183], and has entered phase I clinical development [27, 28, 183], although there are currently no clinical data available in the literature. The muscle versus prostate selectivity of BMS-564929 was studied by measuring AR luciferase reporter gene expression in vitro, and this compound was found to be approximately 20 times as potent in muscle cells compared to prostate cells [183].

*BMS-564929 for the Treatment of Muscle Wasting* The anabolic and androgenic effects of BMS-564929 compared to testosterone were studied in an ORX mature rat model [183]. Starting 14 days after castration, rats were treated orally with BMS-564929 (0.00001–10 mg/kg) or subcutaneously with testosterone propionate (0.03–10 mg/kg). Following a 14-day treatment period, levator ani muscle weights, prostate weights, and serum LH levels were assessed. The $ED_{50}$ (effective dose 50%) of BMS-564929 in levator ani muscle was 0.0009 mg/kg compared to an $ED_{50}$ of 0.14 mg/kg in the prostate, indicating that BMS-564929 is over 150-fold more selective for muscle. Testosterone propionate, in contrast, was only about twice as selective for muscle ($ED_{50}$ 0.21 mg/kg) compared to prostate ($ED_{50}$ 0.42 mg/kg). Thus, BMS-564929 was approximately 200 times as potent as testosterone in stimulating the levator ani muscle. Similar results were seen following 8 weeks of treatment in a separate experiment. One potentially troublesome finding in this study was that BMS-564929 potently suppressed serum LH levels with an $ED_{50}$ of 0.008 mg/kg, or 8 μg/kg [183]. This could have implications for the chronic use of this compound.

***6-N,N-Bis(2,2,2-Trifluoroethyl)Amino-4-Trifluoromethylquinolin-2(1H)-one (LGD-2226)*** Based on available information, potential clinical targets of LGD-2226 (Fig. 2), a quinoline analog, include muscle and bone loss due to male hypogonadism [184, 185]. The quinoline analogs are a novel class of SARMs first described by Ligand Pharmaceuticals [27]. The synthesis of LGD-2226 was recently described [186]. In vitro, the potency of LGD-2226 was similar to that of DHT in an androgen-responsive luciferase reporter assay. In prostate cancer cells, LGD-2226 showed weak partial agonism in activation of the prostate-specific antigen (PSA) promoter [185]. LGD-2226 is reportedly in phase I clinical development [28], but a recent publication suggests that the development of this compound has been abandoned because of preclinical toxicity issues [29]. Discussed below are the results of the only published study of LGD-2226.

*LGD-2226 for the Treatment of Male Hypogonadism* A series of studies was conducted to assess the effects of LGD-2226 on the levator ani muscle, the prostate, and on bone in ORX rats. In a 2-week study comparing LGD-2226 (1–100 mg/kg) to testosterone (1–100 mg/kg), both compounds stimulated the levator ani muscle dose dependently, with sham control levels achieved at 3 mg/kg. Testosterone stimulated prostate growth more potently than LGD-2226, as observed with other SARMs, although LGD-2226 fully restored prostate weight at 100 mg/kg. Likewise, serum LH suppression by LGD-2226 was less potent than that of testosterone [185]. To assess the bone effects of LGD-2226, a 6-week study in ORX rats was performed. Doses of 1, 3, and 10 mg/kg were compared to 100 mg/kg of the synthetic androgen fluoxymesterone. The muscle selectivity displayed by LGD-2226 in the 2-week study was also observed following 6 weeks of treatment. At 3 mg/kg, LGD-2226 fully inhibited the increase in LH caused by ORX. Urinary levels of deoxypyridinoline, a marker of bone degradation, were significantly reduced by LGD-2226 and fluoxymesterone. In cancellous bone, the rates of mineral apposition and bone formation were significantly reduced by LGD-2226, suggesting reduced bone turnover [185]. A 16-week study in ORX rats was also performed to determine the effects of LGD-2226 (1, 3, and 10 mg/kg) in cortical bone and total BMD. Total BMD was significantly increased above sham levels at the two highest doses of LGD-2226. The periosteal mineral apposition and bone formation rates were also significantly increased by LGD-2226. Finally, bone strength was significantly enhanced by LGD-2226 compared to sham control [185]. The results of these studies show that LGD-2226 simultaneously decreased bone turnover in cancellous bone and increased bone formation in cortical bone.

***2-(4-Dimethylamino-6-Nitro-1,2,3,4-Tetrahydroquinolin-2-yl)-2-Methylpropan-1-ol (S-40503)*** This SARM is a tetrahydroquinoline analog (Fig. 2), a chemical class based on the structures of the antiandrogens bicalutamide and hydroxyflutamide and steroidal androgens [27]. The most recent published information indicates that S-40503 is still in preclinical development [28], and thus there are few data on this compound available in the literature. The only peer-reviewed paper that has been published shows that S-40503 could potentially be useful in the treatment of male hypogonadism and possibly postmenopausal osteoporosis [187], and this work is discussed below.

*S-40503 for Male Hypogonadism and Osteoporosis* A series of studies were conducted to examine the effects of S-40503 on the levator ani muscle and prostate in ORX and intact male rats, and on bone in both ORX male and OVX female rats. In ORX rats, S-40503 was injected subcutaneously at doses of 1–30 mg/kg/day for 4 weeks beginning one day after castration. For comparison, groups of rats were administered DHT at doses of 0.01–10 mg/kg. Both S-40503 and DHT increased levator ani muscle mass dose dependently compared to ORX control. At the highest dose (30 mg/kg), S-40503 significantly increased levator ani muscle weight compared to sham control, similar to DHT. Femoral BMD was also increased significantly compared to ORX control by S-40503 at 30 mg/kg. However, unlike the other SARMs discussed, S-40503 had a substantially greater stimulatory effect on the prostate, with the 30-mg/kg dose restoring the prostate to approximately 75% of sham control. Dihydrotestosterone at 10 mg/kg increased prostate weight to nearly 1.5 times that of the sham control. Similar effects were observed on the seminal vesicles [187]. In intact rats, S-40503 at 30 mg/kg/day for 4 weeks did not stimulate the prostate while significantly increasing levator ani muscle mass [187]. To assess the effects of S-40503 in an OVX rat model of osteoporosis, S-40503 (30 mg/kg) was administered for 8 weeks to OVX rats starting 4 weeks after ovariectomy. Dihydrotestosterone (10 mg/kg) and estradiol (20 μg/kg) were included for comparison. Both S-40503 and DHT treatment significantly increased cortical bone BMD and periosteal mineral apposition rate above sham control level, while estradiol had no effect on cortical bone BMD and significantly reduced the periosteal mineral apposition rate below sham control level. Estradiol did, however, cause a significant increase in cancellous bone BMD compared to OVX control, while S-40503 and DHT failed to produce any significant changes in cancellous bone BMD. Biomechanical bone strength was significantly enhanced by S-40503, but not DHT, compared to OVX control [187]. These results showed that S-40503 and DHT primarily stimulated bone formation while estradiol prevented bone resorption.

## 4 FUTURE OF SERMS AND SARMS

The drawbacks of steroidal therapies, for example, HRT and androgen replacement, the side effects of earlier generation SERMs, and the emerging needs of our aging population have led to intensive research and development efforts to discover newer and more efficacious nonsteroidal SERM and SARM therapies that offer the benefits of steroid-based therapies while avoiding their associated side effects. Probably the biggest obstacle in new SERM development so far has been uterine side effects, which has led to a number of compounds being dropped from clinical development, including droloxifene, idoxifene, and levormeloxifene [188]. While raloxifene is relatively devoid of uterine side effects, its other side effects, for example, hot flashes, stroke, and thromboembolism, will likely restrict its use in healthy women. Among the SERMs in late-stage clinical development, ospemifene appears to be one of the more promising agents. In addition to the investigational SERMs already described, there are several new compounds still in early development such as GW5638 (a triphenylethylene derivative), HMR-3339 (a steroid-based SERM), ERA-923 (an indole derivative), and CHF-4056 and CHF-4227.01 (both benzopyran derivatives). The clinical potential of these compounds is still largely unknown, but the future of SERM development looks very promising.

In contrast to SERMs, SARMs are relatively new, and thus all of these agents are still in preclinical or early clinical development. The nonsteroidal SARMs offer a distinct advantage over steroidal androgens in that they are not substrates for aromatase or 5α-reductase and have tissue-selective activity, similar to SERMs. Of the SARMs that have entered clinical trials, S-1, S-4, and BMS-564929 appear to be the most promising based on their preclinical data, and clinical trial results for these compounds are eagerly awaited. Besides the SARMs discussed above, there are several new agents in the very early stages of development described in the recent literature. In preclinical studies, another aryl propionamide SARM, C-6, has shown promise as a potential male contraceptive agent [189]. Two new chemical classes of SARMs, arylisothiocyanates [190] and benzimidazoles, for example, JNJ-26146900 [191], have shown antiprostate cancer effects in vitro and in vivo. A third new SARM chemical class based on the structure of mifepristone (RU486) has also been described [192]. Finally, an interesting new SARM-like compound, fispemifene, has been shown in phase I–II trials to significantly increase testosterone levels in men with secondary hypogonadism [193]. Fispemifene was originally developed as a SERM; however, it is currently being developed as a SARM. Its mechanism may differ from other SARMs in that it functions through the ER to increase testosterone levels in hypogonadal men by inhibiting estrogen feedback inhibition in the pituitary [194]. In summary, SERMs and SARMs research has uncovered a number of promising new ER- and AR-targeted agents for the treatment and/or prevention of breast cancer, osteoporosis, vaginal atrophy, male hypogonadism, and BPH, and we can look forward to more advances in this exciting field in the future.

## 5 CONCLUSIONS

Prior to the discovery of nonsteroidal SERMs and SARMs, the only available treatment modalities for conditions such as menopausal symptoms and postmenopausal osteoporosis in women, and the symptoms associated with hypogonadism in men, were steroid based. Recent clinical trial data have shown that the long-term use of HRT in postmenopausal women is associated with an increased risk of breast cancer and may increase the risk of CHD and dementia, contrary to the results of previous observational studies. There are also concerns that androgen replacement therapy in hypogonadal men may pose a risk to prostate health, in addition to the difficulties inherent with the delivery of steroidal androgens. Thus, there is now great interest in developing nonsteroidal, orally bioavailable therapies, that is, SERMs and SARMs, that can provide the respective benefits of estrogens and androgens while minimizing their associated side effects. Side effects associated with the currently approved SERMs—tamoxifen, toremifene, and raloxifene—preclude their widespread use in a healthy population; however, newer generation SERMs currently in development, such as ospemifene, offer great promise for the treatment of urogenital atrophy, osteoporosis, and, potentially, the chemoprevention of breast cancer. While SARMs are relatively new on the scene, the first such agents being described in 1998, available preclinical data for a number of investigational agents show that these compounds hold tremendous potential for the treatment of male hypogonadism, BPH, prostate cancer, and osteoporosis in both men and women. However, due to the lack of published clinical data on any of these compounds, the positive preclinical observations remain to be proven clinically. Nevertheless, the ongoing development of next-generation SERMs and SARMs offers great promise to meet the emerging and unmet medical needs of our aging population.

# IN-DEPTH LOOK: ANTI-TNF-α THERAPIES

Satadal Chatterjee and Shobhan Gaddameedhi

*Department of Pharmaceutical Sciences, College of Pharmacy, Nursing, and Allied Sciences, North Dakota State University, Fargo, North Dakota*

## 1. INTRODUCTION

### 1.1 Tumor Necrosis Factor-α Discovery

Long before the discovery of *tumor necrosis factor-α* (TNF-α), a German physician named P. Bruns reported the regression of tumors after bacterial infection. This led an American oncologist, William Coley, to use bacterial extracts (referred to as Coley's toxins) for the treatment of human cancers [1]. William Coley first observed the phenomenon of tumor necrosis when he saw that the tumors of some of his cancer patients shrank after they had acquired streptococcal infections. Subsequently, in 1975, Lloyd Old and his colleagues, at Memorial Sloan Kettering Cancer Center, identified the TNF-α in the serum of bacterium-primed, endotoxin-challenged mice [2]. It was classified along with other cytokines, such as interferon-γ (IFN-γ) and interleukin-2 (IL-2). Due to its ability to cause tumor necrosis TNF-α soon became the next best hope in cancer treatment. It was tested on cancer patients all over the world, but the results were not as promising as expected.

At the same time, another group at Rockefeller University, headed by Anthony Cerami, was trying to unravel the basis of cachexia—a wasting syndrome associated with many chronic diseases such as cancer, human immunodeficiency virus–acquired immunodeficiency syndrome (HIV–AIDS), tuberculosis (TB), and the like. He found that cachexia was associated with lipemia, the accumulation of lipids in the blood due to suppression of the fat-metabolizing enzyme lipoprotein lipase (LPL) [3], and conjectured that the same factor, which is causing cachexia, is also suppressing LPL, thus triggering lipemia. Furthermore, he had surmised that cachexia and associated lipemia might be due to a protective factor produced by the host in order to fight the infection, but its chronic production became a threat to the body. They tested and validated this hypothesis in a mouse model of endotoxin-induced cachexia [4]. Later, one of Cerami's postdoctoral associates, Bruce Beutler, successfully isolated this factor and their team named this factor as "cachetin" [5, 6]. It was thought to be a unique protein until Beutler sequenced it and found that its sequence was similar to that of human TNF-α discovered earlier by Old's group [7]. The biological activities of TNF-α and cachetin were also found to be alike [8].

The rediscovery of TNF-α as cachetin and elucidation of its role in cachexia explained the side effects seen in cancer patients treated with TNF-α [9]. Beutler's team later found that blocking TNF-α activity using antibodies reduced infection-induced inflammation and endotoxin-induced lethality [10]. Cloning of TNF-α by Goeddel and colleagues in 1984 made sufficient recombinant materials available for study [11]. The studies demonstrated that TNF-α was a multifunctional cytokine that mediates key roles in acute and chronic inflammation and infection. Today, anti-TNF-α drugs are being successfully used in the treatment of various inflammatory diseases such as rheumatoid arthritis (RA) and Crohn's disease. In later years, research showed that TNF-α is involved in the progression of cancer in many

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

other ways besides causing cancer-associated cachexia. Anti-TNF-α therapy aiming to block TNF-α, directly or indirectly, is now being investigated for treatment as well as for supportive care in cancer patients. Currently, it appears to be one of the promising approaches in resistant and nonresistant tumors as well as for cancer-associated cachexia. This chapter will review some of the approaches being exploited to block TNF-α and the anti-TNF-α drugs that have made it to clinical trials or have been approved by U.S. Food and Drug Administration (FDA) for anticancer therapy.

### 1.2 Structure–Function Relationships in the TNF and TNFR Superfamily

TNF-α and lymphotoxin-alpha (LT-α, also called TNF-β) were first identified as products of macrophages and lymphocytes that caused the lysis of certain types of cells, especially tumor cells [2, 12–14]. When the complementary deoxyribonucleic acids (cDNAs) encoding LT-α and TNF-α were cloned [11, 15], they were similar to one another [8], and, eventually, it became clear that they were members of a gene superfamily. Even the receptors for these proteins constitute a TNF-α receptor (TNFR)-related gene superfamily. It is now established that the TNF superfamily is a growing family of cytokines with 19 peptides signaling through 29 receptors [16]. A nomenclature system adopted for these proteins and their receptors is comprised of the term TNFSF for TNF superfamily and TNFRSF for TNFR superfamily and a number ranging from 1 to 19 [17]. The members of the TNFSF along with their receptors as well as their extracellular and cytoplasmic domains are shown in Figure 1 [16]. The functions of all these proteins are yet to be completely elucidated.

Almost all of the ligands of TNFSF are expressed by cells of the immune system, such as B cells, T cells, natural killer (NK) cells, monocytes, and dendritic cells. The only exception to this is the vascular endothelial cell growth inhibitor (VEGI), which is expressed by endothelial cells. In contrast, receptors of TNFRSF are expressed by a wide variety of cells, accounting for the diversity in biological effects observed with these cytokines. The activities mediated by TNFSF ligands and their receptors range from tissue damage to organogenesis. Most of the members are involved in the regulation of cell proliferation and apoptosis and some of them, namely, TNF-α, LT-α, Fas ligand (FasL or CD95L), CD30 ligand (CD30L), and CD40 ligand (CD40L) have pro-inflammatory properties. TNF-related apoptosis-inducing ligand (TRAIL) appears to be unique since it antagonizes autoimmune inflammation, in part, by blocking cell cycle progression [17]. In physiological conditions, members of TNF/TNFRSF are essential for hematopoiesis, protection from bacterial infection, immune surveillance, and tumor regression. Dysregulation of these processes leads to various diseases including AIDS, Crohn's disease, RA, heart failure, asthma, Systemic lupus eythematosus (SLE), as well as cancer [16].

All ligands in TNFSF, except LT-α and VEGI, which are secreted, are type 2 transmembrane proteins (single-pass transmembrane with a cytoplasmic N-terminus and an extracellular or luminal C-terminus). They can have both membrane-bound "pro" and cleaved, soluble "mature" forms [18]. Most members are released from the cell surface by proteolysis through distinct proteases. For example, TNF and receptor activator of nuclear factor-κB (NF-κB) ligand (RANKL) are cleaved by metalloproteases of the ADAM (a disintegrin and metalloprotease domain) family [19, 20], CD95L by matrilysin [21], and B-cell-activating factor (BAFF), ectodermal dysplasin (EDA), TNF-like weak inducer of apoptosis (TWEAK), and a proliferation-inducing ligand (APRIL) by members of the furin family [22, 23]. Both the forms—membrane bound as well as soluble ligand—are active and, infact, in certain cases the soluble ligand can compete with the membrane-bound ligand for the receptor. When bound to the receptor, some soluble ligands act as agonists while others act as antagonists. For instance, CD95L kills human peripheral blood T cells while soluble CD95L blocks this killing [24]. Furthermore, the transmembrane expression of these ligands indicates that they are meant to act locally. However, only under nonphysiological conditions, when they are cleaved, they act on different cell types and prove harmful. This seems to be true for TNF-α, which when released into the circulation, binds to various cell types and mediates various diseases, including cancer [16].

Ligand protomers are composed of antiparallel β-pleated sheets with antiparallel β strands that form a "jelly role" β-structure, which is typical of TNFSF [25]. To be biologically active, ligands have to self-assemble as noncovalent trimers and they do so by interacting at hydrophobic interfaces [26]. The TNFSF ligands share 25–30% amino acid similarity, and this mainly involves the internal aromatic residues responsible for trimer assembly. The external surfaces of ligand trimers show little sequence similarity, and this account for their receptor selectivity [27]. As shown in Figure 1, most of the ligands bind to a single receptor, whereas some can bind to more than one.

A threefold stoichiometry defines the entire signaling cascade mediated by TNF/TNFR SF proteins. The trimeric TNFSF ligand forms a 3:3 symmetric complex with the receptors of TNFRSF. The receptors adopt an elongated structure on the cell membrane, and these

**Figure 1** Description of the interaction of members of the TNFSF with their receptors as well as their cytoplasmic and extracellular domains. (Adapted by permission from Nature Publishing Group [16].)

elongated receptor chains fit into the grooves between protomers of the ligand trimer [27]. Interaction of TNF-α with its receptors is shown in Figure 2 [28].

Receptors of TNFRSF, on the surface of the cell membrane, function as pre-formed complexes rather than as individual receptor subunits. They tend to oligomerize once the ligand binds to it. After ligand binding, the receptor cytoplasmic tails form a 3:3 internal complex with signaling proteins such as TNFR-associated factors (TRAF) and Fas-associated death domain (FADD). Hence, the cytoplasmic domains of these receptors serve as docking sites for various signaling molecules.

Unlike the ligands of TNFSF, receptors in TNFRSF are type 1 transmembrane proteins (single-pass transmembrane with a cytoplasmic C-terminus and an extracellular or luminal N-terminus). The extracellular region of these receptors has a characteristic "cysteine-rich domain" (CRDs), and this is the hallmark of receptors of TNFRSF. CRDs are typically 40 amino acid pseudorepeats and are defined by 3 intrachain disufides generated by 6 highly conserved cysteines [29]. The receptors in TNFRSF can be classified as signaling receptors or nonsignaling "decoy" receptors (DCRs). Based on the type of cytoplasmic region, signaling members of TNFRSF can be further classified as those that contain

**Figure 2** Interaction of TNF-α with its receptors. (Adapted by permission from Nature Publishing Group [28].)

a cytoplasmic death domain (DD), called death receptors (DRs), and those that are devoid of a cytoplasmic death domain. A DD is a region of approximately 80 amino acid residues and is responsible for death ligand-induced apoptosis that constitutes the cell-extrinsic pathway of apoptosis [30]. The second subgroup of signaling members of TNFRSF lacks a cytoplasmic death domain and instead displays a homologous sequence motifs that mediates interaction with specific adaptors from the TRAF family [31]. In case of TRAF1, TRAF2, and TRAF 5, the interaction requires a Pro-Xaa-Gln-Xaa-Thr motif, while in the case of TRAF6, this interaction is mediated through a distinct motif: Gln-Xaa-Pro-Xaa-Glu [32]. TRAFs link these receptors to serine/threonine protein kinase cascades that regulate gene transcription, such as the inhibitor of κB kinase (IKK), JUN N-terminal kinase (JNK)/p38 and extracellular-signal-regulated kinase/mitogen-activated protein kinase (ERK/MAPK) pathways. In contrast, DCRs are the nonsignaling subset of the TNFRSF that compete with the signaling receptors for binding to the ligand and, hence, attenuate the ligand–receptor signaling [33]. TNFRSF includes 4 decoy receptors (DCRs), namely, DCR1, DCR2, DCR3, and osteoprotegerin (OPG). Hence, the unique structural attributes of the ligands and receptors in the TNF/TNFR superfamily couple them directly to signaling pathways for cell proliferation, survival, and differentiation [27].

### 1.3 TNF-α Signaling through Its Receptors

TNF-α signaling is mediated through two distinct transmembrane, glycoprotein receptors of the TNFRSF: TNFR-1 (also known as p55/60 or CD120a receptor) and TNFR-2 (also known as p75/80 receptor or CD120b receptor). Like other members of the TNFRSF family, TNFR-1 and TNFR-2 carry four CRDs in the extracellular region [34] and assemble as homotrimers on the cell surface, in response to ligand binding. However, there have been some reports suggesting that TNFR chains preassemble into complexes on the cell surface prior to ligand binding, utilizing a conserved domain in the extracellular region called "preligand assembly domain" (PLAD) [35]. Both the receptors of TNF-α are present on all the cell types except endothelial cells. However, their distribution varies with the cell types. While TNFR-1 is ubiquitously expressed on mammalian cells, TNFR-2 expression is mainly restricted to endothelial and immune cells [16, 36]. Thus, in a vast majority of cells, TNFR-1 appears to be the key mediator of TNF-α signaling, whereas in the lymphoid system TNFR-2 seems to play a major role. Also, TNFR-1 expression is constitutive, while that of TNFR-2 is inducible.

In response to ligand binding, both the receptors shed their extracellular domains from the surface of the cells. This proteolytic cleavage is carried out by enzymes of the matrix metalloprotease (MMPs) family, which are zinc-dependent endopeptidases. In case of TNFR-2, this MMP is a TNF-α converting enzyme (TACE), while in case of TNFR-1, the enzyme responsible for cleavage is still undefined. However, TNFR-1 cleavage is biologically significant since cleavage resistant TNFR-1 mutations are linked with dominantly inherited autoinflammatory syndromes (TNFR-1-associated periodic syndromes; TRAPS) [37] Interestingly, the shed extracellular domains retain their ability to bind TNF-α. Therefore, one of the hypothesis says that the shed domains serve as natural antagonists to TNF-α binding to the membrane-bound receptors [38]. Based on the TNF-α neutralizing ability of soluble receptors, dimeric IgG fusion proteins, for example, etanercept, have been synthesized that mimic the soluble receptors and prevent TNF-α binding to the membrane-bound receptor to initiate the signaling cascade. Alternatively, the second hypothesis says that the shed domains serve as ligand

passers (delivery peptides) for the circulating TNF-α, that is, they deliver TNF-α to TNFR for signaling when concentrations of TNF-α are low [17, 39]. The binding affinities for TNF-α differ among the two receptors. TNFR-1 has been shown to have higher affinity for soluble (17-kDa) TNF-α (sTNF) [40], while TNFR-2 can only be fully activated with membrane-bound TNF-α (memTNF) and not sTNF-α [41]. It has been proposed that under some experimental conditions, TNFR-2 may also serve as ligand passer for the circulating TNF-α [42].

TNFRs themselves have no metabolic capability and must bind intracellular proteins in order to regulate the signal transduction events. The major difference between the two receptors lies in the presence of cytoplasmic DD in TNFR-1 and its absence in TNFR-2. Therefore, TNFR-1 is a DR and has the capability of carrying out ligand-induced caspase activation and apoptotic cell death [43]. In contrast, TNFR-2 is a TRAF-interacting receptor. Due to the presence of different cytoplasmic domains, both receptors also differ in their intracellular signaling pathway. Therefore, depending on the receptor type activated by TNF-α and the associated downstream signaling molecules, TNF-α has an optional capacity to induce apoptosis or promote cell survival. The TNF-α signaling pathways are illustrated in Figure 3 [36].

TNF-α is synthesized as a membrane-bound propeptide (pro-TNF-α of 26 kDa). It is secreted as soluble, 51 kDa, homotrimeric cytokine (sTNF) after cleavage by the metalloprotease enzyme (TACE). The sTNF tends to dissociate into 17-kDa protomers, at concentrations below nanomolar range, thereby loosing its bioactivity [28]. The pro-TNF-α is also functional and binds to TNFR via direct cell-to-cell contact, as shown in Figure 2 [28].

***TNFR-1 Signaling*** As explained previously, subsequent to the binding of homotrimeric ligand TNF-α to the TNFR-1, trimerization of TNFR-1 takes place. In the absence of ligand, a protein called silencer of death domain (SODD) functions to mask the intrinsic property of the DD of TNFR-1 to self-aggregate and signal the induction of apoptosis [44]. But as soon as the ligand binds to the receptor, SODD dissociates from TNFR-1 complexes [45] and the DD of TNFR-1 complexes can now interact with an adaptor protein such as TNFR-associated death domain (TRADD) [46]. TNFR-1-bound TRADD serves as an assembly platform for binding of various other adaptor proteins such as FADD and DD containing serine–threonine kinase receptor interacting protein (RIP) or TRAF-2 [47]. RIP is also capable of interacting with TRAF-2 via its amino-terminal kinase domain and its central intermediate domain [48]. These adaptor proteins then recruit key proteins that are responsible for further signaling events.

**Figure 3** TNF-α signaling pathways. (Adapted by permission from Elsevier Ltd. [36].)

TNFR-1 is indirectly linked to FADD by the adaptor protein TRADD, which is also responsible for bridging TNFR-1 to TRAF-2 and the IKK complex [49]. Receptor-bound FADD in turn interacts with caspase-8/10 via the death effector domains contained in the amino-terminal parts of both molecules [50, 51]. FADD-mediated recruitment brings several pro-caspase-8/10 molecules in close proximity and thereby facilitates autoproteolytic activation of these proteases. Thus, when TNFR-1 signals apoptosis, FADD binds pro-caspase-8/10, which is subsequently activated to active caspases and results in apoptosis [52]. On the other hand, when TNFR-1 signals cell survival, TRAF-2 is recruited to the complex, which inhibits apoptosis by recruiting the cytoplasmic inhibitor of apoptosis protein (cIAP) [53, 54]. Hence, depletion of TRAF-2, which is a major part of TNFR-1 signaling complex, sensitizes cells for apoptotic action of TNF-α [53, 55, 56].

Subsequent to binding of TRAF-2, transcription factor NF-κB gets activated via RIP. NF-κB comprises a group of transcription factors with five members, namely, c-Rel, Rel A, Rel B, NF-κB1, NF-κB2, and they are characterized by the presence of Rel homology domain (RHD), which serves as their dimerization, DNA binding, and principal regulatory domain [57]. At the C-terminus of RHD, there is a nuclear localization signal (NLS), which is rendered inactive by the bound inhibitors of the NF-κB and IκB proteins. IκB proteins are the specific inhibitors of NF-κB and bind to the RHD through their core domain composed of six to seven ankyrin repeats and thereby mask NLS. Activation of NF-κB, in response TNF-α binding to TNFR-1 or in response to various other cytokines, like IL-1, mostly depends on the phosphorylation-dependent ubiquitination of the IκB proteins. This involves two protein complexes the IKK complex (for phosphorylation of IκB proteins) and the $E3^{I\kappa B}$ ubiquitin ligase complex (for poly-ubiquitination of IκB proteins) [58]. Hence, subsequent to phosphorylation and poly-ubiquitination, the IκB proteins undergo degradation through the 26 S proteosome. The liberated NF-κB dimers have a free NLS to migrate to the nucleus where they can carry out the transcription of the target genes [59]. The target genes for the NF-κB group of transcription factors include a huge number of inflammation-related genes that get activated in response to cytokines such as TNF-α, IL-1, and the like [60]. Besides, the target genes also include a variety of antiapoptotic factors, and in this way NF-κB regulates TNFR-1-mediated triggering of cell apoptosis [61]. Thus, the net effect of TNF-α-mediated activation of NF-κB, through TNFR-1, is cell proliferation and inflammation.

Binding of TRAF-2 also initiates a cascade of phosphorylation events resulting in the activation of transcription factors such as c-Fos/c-Jun and activation transcription factor-2 (ATF-2) via the MAPK and JNK/p38 pathway [62]. It has been shown that the TRAF-2 adaptor is necessary for coupling the JNK pathway to TNFR-1 [63, 64]. c-Jun belongs to a group of basic region–leucine zipper proteins that dimerize to form the transcription factor commonly known as activator protein-1 (AP-1) [65]. The AP-1 proteins play an important role in cell proliferation, differentiation, and induction, as well as prevention of apoptosis [65]. TNF-α-induced activation of JNK has also been implicated in upregulation of collagenases [66], the chemoattractant monocyte chemotactic protein-1 (MCP-1) [67] and E-selectin [68].

***TNFR-2 Signaling*** TNFR-2 is a non-DD-containing receptor, but signaling through this receptor has also been associated with induction of apoptosis. With the use of agonistic TNFR-2-specific antibodies, it has been demonstrated that exclusive triggering of this receptor is sufficient to induce cell death in some cells [69–71]. However, unlike TNFR-1 it cannot directly engage an apoptotic program but relies on the induction of endogenously produced memTNF-α, which subsequently activates TNFR-1 [72, 73]. The action of endogenously produced memTNF-α on TNFR-1 is drastically enhanced by the existing stimulation of TNFR-2 [28]. Additionally, a TNFR-2-dependent depletion of TRAF-2 and antiapoptotic cIAP proteins also leads to induction of apoptosis [28, 74].

### 1.4 Biology of TNF-α

TNF-α is produced mainly by macrophages but also by many other cell types, such as lymphoid cells, mast cells, endothelial cells, fibroblasts, and neuronal cells. It was first characterized as a cytokine that caused tumor necrosis in vivo. Contrastingly, it also exhibited antitumor activity by inducing apoptosis. Later, it was identified that TNF-α is one of the pleiotropic cytokines with significant biological functions. This includes (a) modulation of growth, differentiation, and metabolism in various cell types; (b) mediation of cachexia by stimulating lipolysis, inhibiting LPL activity in adipocytes, and by stimulating hepatic lipogenesis; (c) initiation of apoptosis in cancerous or transformed cells, epithelial cells, virally infected cells, and T lymphocytes; and (d) inflammation [75]. sTNF is produced in large amounts in response to lipopolysaccharide (LPS) and other bacterial products. In concert with other cytokines, it also mediates septic shock [76].

Like IL-1, TNF-α is also a powerful inducer of the inflammatory response and is the most important regulator of innate immune response. Inflammatory

responses to TNF-α are mediated both directly and through stimulation of the expression of IL-1 and also via more distal pro-inflammatory cytokines. Secondary mediators that are known to be induced by systemically administered TNF-α include cytokines [IL-1, IL-2, IL-4, IL-6, IL-10, IL-12, IL-18], IFN-γ, transforming growth factor-β (TGF-β), leukemia inhibitory factor (LIF), and macrophage migration inhibitory factor (MIF), hormones (cortisol, epinephrine, glucagon, insulin, and norepinephrine), and many other molecules such as acute phase proteins (APP), leukotrienes, oxygen free radicals, platelet-activating factor (PAF), nitric oxide (NO), and prostaglandins (PGs) [17]. TNF-α also plays an important role in regulation of the T-helper type 1 cells (TH-1) immune response, in turn resulting in increased levels of $CD4^+$ T-cell activation and IFN-γ production. This is particularly important in the pathogenesis of a number of chronic inflammatory diseases such as inflammatory bowel disease and RA, in which a positive feedback loop linking the autoimmune and the inflammatory or innate immune responses has been established [77]. In response to various stimuli and physiological conditions, TNF-α mediates diverse effects in different organs and tissues as shown in Figure 4 [78, 79]. Under various pathological conditions, such as trauma, ischemia, and inflammatory diseases, the expression and release of TNF-α can be rapidly increased in the brain [80]. Clinical studies have found increased expression of TNF-α in cerebrospinal fluid (CSF), plasma, or postmortem brain tissue in patients following stroke, brain injury, HIV dementia, multiple sclerosis, alcoholism, and Alzheimer's disease [80]. It has been shown that central nervous system (CNS) damage can also increase TNF-α active transport into the brain [81]. Accumulating evidence indicates that TNF-α has been implicated as contributing to both neuroprotection and neurodegeneration [82]. Acute inhibition of endogenous TNF-α reduces ischemic and traumatic brain damage in rodent models, suggesting that TNF-α contributes to the brain damage [83, 84].

In vitro studies have demonstrated that TNF-α increases lipolysis in both rodents and human adipocytes [85, 86]. It is not clear how TNF-α activates lipolysis, but studies have shown that TNF-α downregulates the expression of the lipid droplet-associated protein perilipin (PLIN), which is thought to modulate the accession of hormone-sensitive lipase (HSL) to the surface of the fat droplet [87]. A recent clinical trial

**Figure 4** Various targets of TNF-α action. (Adapted by permission from Nature Publishing Group [78] and Elsevier Ltd. [79].)

in humans demonstrated that anti-TNF-α treatment increased high-density lipoprotein (HDL) without influencing low-density lipoprotein (LDL), which suggests that TNF-α is involved in the development of a high-risk lipid profile [88].

As discussed previously, TNF-α is also a potent activator of NF-κB, and this has been implicated in decreased muscle protein synthesis [89–91]. TNF-α activation is also responsible for the reduction of MyoD protein, a transcription factor that modulates signaling pathways involved in muscle development [92]. It has been shown that TNF-α-mediated skeletal muscle degeneration is associated with cachexia, a debilitating syndrome characterized by extreme weight loss and whole-body wasting [93–95]. Pathophysiology of cachexia and role of TNF-α in mediating its pathophysiology has been discussed in detail in a later section.

### 1.5 Regulation of TNF-α Expression

Macrophages/monocytes form the first line of defense against invading pathogens and also for chemoattraction of other components of the immune system to the site of entry, to effectively prevent invasion by the pathogen. One of the very early responses of macrophages to the invading pathogens is the accumulation of messenger RNA (mRNA) coding for inflammatory and chemotactic polypeptides, including TNF-α, IL-1α and β, and members of the chemokine family (IL-8, MIF), subsequently followed by the secretion of the respective protein. TNF-α is one of the "immediate early" effector proteins induced by a variety of stimuli. Thus, in blood monocytes and tissue macrophages, levels of TNF-α mRNA sharply increase 5- to 50-fold, within 15–30 min after exposure to an inciting agent [96]. Furthermore, the efficiency of mRNA translation can increase over 100-fold [4]. Therefore, TNF-α is one of the major factors secreted by activated macrophages [97], but the quiescent cells produce it only in barely detectable quantities. To regulate the TNF-α expression both transcriptional as well as posttranscriptional mechanisms operate in the body.

Human TNF-α gene locus lies within the highly polymorphic major histocompatibility complex (MHC) class III region located on the shorter arm of chromosome 6 (6p21.3) [98, 99]. The two genes, TNF-α and TNF-β (or LT-α), probably deriving from a duplication of an ancestral gene, are arranged in tandem within a 7-kb stretch of DNA in MHC class III [100]. The TNF-α gene is approximately 3 kbp in length and has four exons and three introns [98].

Most important functional promoter elements of the TNF-α gene have been found in the proximal region up to –200 bp with respect to the transcription start site [101]. TNF-α promoter contains a TNF-responsive element (between –101 and –125 bp) [102]. The regulation by TNF-α of its own promoter (autocrine stimulation) through the TNF-responsive element has been demonstrated in erythroleukemia cells [102]. TNF produced an 8- to 10-fold activation of the human TNF promoter. The TNF-responsive element contains a palindrome, 5′ TGAGCTCA 3′, that resembles the consensus binding sequences for the transcription factors, AP-1, adenosine monophosphate (CAMP)-responsive element binding protein (CREB), and ATF, but the involvement of these transcription factors in the autocrine stimulation is still unproven.

There are a number of biological and chemical substances that trigger the expression of TNF-α. This includes LPS, phorbol esters, mutagens such as dimethylnitrosamine, toxins such as staphylococcal exotoxin B, various vitamins, and cytokines [103, 104]. Many of these have been shown to induce activation of NF-κB transcription factor, thereby leading to NF-κB-induced transcription of the TNF-α gene. Besides this, many tumor cell lines have been found to constitutively express TNF-α mRNA, or can be induced to accumulate the mRNA on induction with any of the agents mentioned above [105, 106]. Many inhibitors of TNF-α mRNA expression have also been reported, and they find clinical application as immunosuppressants, anti-inflammatory, or anticancer agents. This includes dexamethasone, pentoxifylline, protein kinase C inhibitors, cyclosporin C, prostoglandin E2 (PGE2), thalidomide, and its analogs [103, 104]. TNF-α shows tissue-specific expression. Most TNF-α mRNA containing cells do not release TNF-α protein, suggesting that TNF-α in these cells is predominantly regulated by a posttranscriptional mechanism [103].

Posttranscriptional regulation constitutes one of the major and most well-studied means of regulation of TNF-α gene expression [107]. It is generally mediated by the 5′ or 3′ untranslated regions (UTRs) of the mature mRNA, which flank the protein coding sequence. Sequences rich in adenine and uridine (AU-rich elements; ARE) are present in the 3′ UTRs of mRNAs and are recognized by a specific subset of RNA-binding proteins known as ARE-binding proteins (ARE-BPs). AREs are among the predominant *cis*-acting factors that regulate mRNA stability [108]. AREs are composed of a variable number of copies of the AUUUA or UUAUUUAUU nonamers. Mammalian TNFα mRNAs possess a 3′ UTR of almost 800 nucleotides, within which is a well-conserved ARE containing 7 or 8 copies of the AUUUA sequence. The presence of these 3′ AREs was responsible for both the suppression of TNF-α mRNA expression in the unstimulated state as well as the derepression that occurs following

stimulation of macrophages with bacterial endotoxin [109, 110].

The AREs are known to be recognition sequences for several RNA-binding proteins (ARE-BPs) of which only a few have been characterized to date, for example, tristetrapolin (TTP) and Tpl2 [111–114]. Some of these proteins appear to be involved in determining TNF-α mRNA stability, while others are involved in translational silencing. The exact mechanism by which AREs mediate the destabilization of mRNAs is still under intense investigation. Although the current understanding favors that AREs lead to shortening of the poly-A tail (deadenylation) [115, 116] and/or removal of the 5′ cap (decapping) [116]. Targeted mRNA may then be degraded from the 3′ to 5′ end either through the recruitment of 5′–3′ exonucleases or through the sequestration of a complex of 3′–5′ exonucleases called exosome [109, 117–119].

Recently, involvement of micro-RNAs (miRNAs) in ARE-mediated mRNA instability has been reported [120]. miRNAs are genomically encoded short noncoding single-strand RNA species found in a wide variety of organisms [121]. Based on the degree of complementarity to the target mRNA sequence, binding of the miRNA to the mRNA results in translational repression of the protein-coding genes or cleavage of mRNA [122]. In regard to the ARE-mediated mRNA instability of TNF-α, it was found that a miRNA, miR16, is involved in mRNA instability of TNF-α in Drosophila S2 and HeLa cells [120]. By analyzing the sequence of miRNA, it was found that miR16 contains eight bases that can pair with ARE in TNF-α mRNA and has no fortuitous match with TNF-α mRNA in other regions. miR16 also interacts with TTP, and it has been speculated that TTP is a factor that assists miR16 targeting to ARE sequences due to its interaction with eiF2C/argonaute (AGO) family members, which are the components of RNA induced silencing complex (RISC). Also, using an RNAi screen it has been shown that Dicer and argonaute, the key components of the miRNA/RNAi system, are required for the ARE-mediated mRNA decay in Drosophila S2 and HeLa cells. This study suggests that both ARE-BPs and miRNA are involved in recognition of ARE sequence and are essential for ARE-mediated mRNA degradation.

Several studies have suggested the role of microribonucleoproteins (microRNP)—the slicer in miRNA-mediated decay, as regulators of ARE-binding miRNAs. First, RISC, the functional microRNP, includes two ARE-associated proteins: plasminogen activator inhibitor-1 RNA binding protein (PAI-RBP1) and fragile-Xmental-retardation–related protein 1 (FXR1) [123]; FXR1 interacts via AGO 2 [124, 125], which is an essential functional effector of the microRNP [126, 127] or the repressor in miRNA-mediated translational repression [128]. Second, miRNAs have been localized to the same cytoplasmic bodies [129–131] as ARE-BPs [131, 132]. It has now been proposed that translation regulation by microRNPs oscillates between repression and activation during the cell cycle [133]. Upon cell-cycle arrest, the ARE in TNF-α mRNA is transformed into a translation activation signal, recruiting microRNP-associated factors, AGO and FXR1 [134, 135]. Recently, it has been shown that human miRNA miR369-3 directs association of these proteins with the ARE to activate translation. Two well-studied miRNAs—Let-7 and the synthetic miRNA cxcr4—likewise induce translation upregulation of target mRNAs upon cell-cycle arrest; yet, they repress translation in proliferating cells. Thus, activation is a common function of microRNPs upon cell-cycle arrest.

AREs and miRNAs target sites have been found to be conserved sequences in mRNA 3′-untranslated regions (3′ UTRs) that post transcriptionally control gene expression [136]. Now, the involvement of miRNAs in ARE-mediated mRNA instability has been well documented and intense investigation is going on to gain a deeper insight into this area [137].

Besides ARE, a novel constitutive decay element (CDE) has also been detected in the 3′ UTR, which carries out mRNA decay in an ARE-independent mechanism [138, 139]. CDE is also located in 3′ UTR of the TNF-α gene, immediately downstream of ARE (80 nt downstream) and is unresponsive to signals that stabilize ARE-containing mRNAs. It also has distinct protein binding specificities and targets the mRNA transcript for rapid decay.

Highly regulated control of biosynthesis of TNF-α ensures that the TNF-α protein is not produced if there is no exogenous stimulation or in tissues that are not destined to synthesize the protein. Localized and transient secretion of TNF-α is physiological, whereas persistent production occurs in certain autoimmune, inflammatory, and malignant diseases and can lead to severe tissue damage. Thus, an understanding of regulators of TNF-α expression can offer novel means of intervention to control its undesirable production.

## 2 INFLAMMATION AND CANCER—THE TNF-α LINK

### 2.1 Inflammation and Neoplastic Progression

Inflammation includes a series of protective responses initiated whenever the host is under a stressor by internal or external environmental stimuli. Acute inflammation, manifested for a short time, is thought to be protective and therapeutic. However, chronic

**Figure 5** Initiators and mediators of inflammation and its role in tumorigenesis. (Adapted by permission from Elsevier Ltd. [140].)

inflammation, which lasts for a very long time, may prove harmful and has been thought to be an underlying cause of many diseases, including cardiovascular diseases, diabetes, arthritis, Alzheimer's disease, pulmonary disease, autoimmune disease, as well as cancer [140]. As shown in Figure 5, release of mediators of inflammation can be elicited by various factors, which in turn can lead to acute or chronic inflammation [140]. The role of chronic inflammation has been implicated in various steps in tumorigenesis, including tumor cell survival, proliferation, invasion, tumor angiogenesis, metastasis, chemoresistance, and radioresistance. As shown in Table 1, chronic inflammation, attributable to infectious, chemical, and physical agents, is thought to be a major risk factor for many types of cancers [140]. The link between inflammation and cancer is further strengthened by the observation that long-term use of non-steroidal anti-inflammatory drugs (NSAIDs) decreases cancer risk by almost 40–50% in certain cases [141].

The concept of inflammation promoting cancer is not new and was first proposed by Rudolf Virchow in 1863, but only in recent years has this became a generally accepted phenomenon [142–146]. In fact, chronic inflammation associated with neoplastic progression is visualized as analogous to inflammation associated with wound healing. The distinguishing feature between the two is that inflammation in wound healing is self-

**TABLE 1 Chronic Inflammation and Associated Cancers**

| Inducer | Inflammation | Cancers |
|---|---|---|
| Tobacco smoke | Bronchitis | Lung cancer |
| *Helicobacter pylori* | Gastritis | Gastric cancer |
| Human papillomavirus | Cervicitis | Cervical cancer |
| Hepatitis B and C virus | Hepatitis | Hepatocellular carcinoma |
| Bacteria, gall bladder stones | Cholecystitis | Gall bladder cancer |
| Gram-uropathogens | Cystitis | Bladder cancer |
| Tobacco, genetics | Pancreatitis | Pancreatic cancer |
| Gastric acid, alcohol, tobacco | Esophagitis | Esophageal cancer |
| Asbestos fibres | Asbestosis | Mesothelioma |
| Epstein–Barr virus | Mononucleosis | Burkitt's lymphoma |
| | Hodgkin's disease | |
| Gut pathogens | Inflammatory bowel disease | Colorectal cancer |
| Ultraviolet light | Sunburn | Melanoma |
| Infections, sexually transmitted diseases | Prostate inflammatory atrophy | Prostate cancer |

limiting, since secretion of anti-inflammatory cytokines follows the pro-inflammatory cytokines, while tumors act as "wounds that never heal" [147]. The chronic inflammation smoldering beneath cancers continues for a long time either due to persistence of initiating factors or a failure of mechanisms required for terminating the inflammatory responses [144].

Tumor microenvironment, also known as tumor stroma, is rich in inflammatory mediators, and the interplay between them plays a major role in fostering carcinogenesis [143, 148]. There is a continuous battle between these inflammatory mediators to strengthen the immune response against tumors on one hand and promote the growth of tumor cells on the other hand. However, neoplastic progression indicates that inflammatory mediators tend to loose the battle as immune system effector molecules and in fact assist the growth and spread of tumors. The specialized leucocytes present in tumor stroma are tumor-associated dendritic cells (TADCs), tumor-associated macrophages (TAMs), and tumor-infiltrating leucocytes (TILs). TADCs normally have an immature phenotype and lack the ability to stimulate T cells, which in turn reflects an ineffective immune response against the tumor growth [149]. TAMs, once activated, can kill the tumor cells. On the other hand, TAMs can also produce growth and angiogenic factors, which promote tumor growth, as well as proteases, which can degrade the extracellular matrix (ECM) and hence stimulate tumor invasion and metastasis [150, 151]. Signaling via T-cell receptor (TCR) is also defective in TILs, which further contributes to an ineffective immune response against the tumor growth [152]. NO and reactive oxygen species (ROS) released from inflammatory cells may induce DNA damage, which further predisposes the cells to a high risk of malignant transformation [153]. In addition to these, tumor cells as well as inflammatory cells present in tumor stroma release cytokines. Some of the cytokines are classified as pro-inflammatory cytokines, for example, IFN-γ, IL-1 and 6, MIF, and TNF-α, while others are growth factors, for example, macrophage-colony stimulating factor (M-CSF) and TGF-β. Yet others serve to regulate the immune cells, for example, IL-4, 5, 10, or promote angiogenesis or vascular permeability, for example, vascular endothelial growth factor (VEGF). Besides these, there are a number of chemokines, for example, MCP-1 and macrophage-derived chemokine (MDC), which are secreted by tumor cells or immune cells. There is strong evidence supporting the direct role of these cytokines and chemokines in malignant progression [154–157]. Moreover, many cytokines and chemokines, including TNF-α, are inducible by hypoxia, which is a major physiological difference between normal and tumor tissue [158]. Furthermore, expression of all these genes is mainly regulated by the transcription factor NF-κB, which is constitutively active in most tumors and is induced by many carcinogens and tumor-promoting factors as well [159–163]. Thus, it is clear that ongoing inflammatory processes within the tumor microenvironment have the capacity to not only produce tumor-promoting factors but to also profoundly suppress the ability of the host antitumor immune responses. A greater understanding of how chronic inflammation leads to cancer, and how inflammatory mediators maintain the balance between pro-inflammatory and anti-inflammatory functions, will help us to design effective anticancer therapy to counter these effects. Also, the information may aid in the development of vaccines and other strategies to augment immune attacks on tumors.

### 2.2 A Paradox—Tumor Necrosis Factor or Tumor-Promoting Factor

TNF-α is one of the key chemical mediators implicated in inflammation-associated cancer. It is secreted by the tumor cells as well as the stromal cells in the tumor microenvironment. As mentioned previously, depending on the receptor type activated by TNF-α and the associated downstream signaling molecules, TNF-α has an optional capacity to induce apoptosis or promote cell survival. Hence, this section will provide some evidence for the paradoxical role of pro-inflammatory cytokine TNF-α as a tumor necrosis factor as well as a tumor-promoting factor.

***Tumor Necrosis Factor—Evidence*** TNF-α, ideal to its name, was found to induce necrosis in a number of animal models, human tumor xenografts, and experimental syngeneic models when administered at high doses [164, 165]. In human tumor xenograft models, it was seen that TNF-α was most effective in its tumoricidal action when it was administered locally at the tumor bearing site [164, 166]. Even greater tumoricidal effect was observed when along with local TNF-α, systemic IFN-γ was also administered. Following administration of both these cytokines, platelet adherence to tumor cells was observed. There was an upregulation of adhesion molecules and other cytokines in the tumor stroma, and macroscopic necrosis as well as apoptosis of tumor cells was witnessed [167].

The antitumor effects of TNF-α were found to be due to direct effects on tumor cells and/or indirect effects on cells of tumor stroma [168]. One of the proposed mechanisms for the tumoricidal action of TNF-α includes direct cytotoxic effect on vascular endothelium [169] and modulation of endothelial procoagulant properties [170]. Tumor-associated vasculature (TAV), which develops due to tumor angiogenesis, has a characteristic

phenotype that distinguishes it from normal vasculature. TAV has a noncontinuous endothelium, an enlarged basal membrane, and aberrant pericyte coverage [171]. Moreover, the vascular hierarchy of arterioles, capillaries, and venules is also rarely found in tumors, resulting in loosely associated pericytes [172]. All this results in a leaky vasculature in the tumor [173] through which blood cells such as lymphocytes and monocytes easily extravasate into the tumor. TNF-α further induces a rapid and prolonged extravasation of red cells into the tumors [174]. The strong extravastion of blood cells results in massive hemorrhagic necrosis of the tumor. This is consistent with an experimental finding in mice bearing methylcholanthrene-A (Meth-A) induced sarcoma tumor cells, where systemic administration of TNF-α consistently caused hemorrhagic necrosis of vascular tumors but not of avascular tumors [175]. Further, in combination with IFN-γ, TNF-α induced downregulation of αVβ3 integrin, which, in turn, resulted in detachment of endothelial cells from the basement membrane and subsequent apoptosis [176]. High-dose TNF-α also has direct cytotoxic effects on endothelial cells, through TNFR-1 signaling pathways, thereby leading to apoptosis. Loss of endothelial cells further enhances the hyperpermeability. Besides the destruction of tumor vasculature, an immediate effect of enhanced hyperpermeability subsequent to treatment with TNF-α lies in augmented accumulation and distribution of the drug in the tumor, which results in better exposure of the tumor cells to the cytostatic agents such as doxorubicin and melphalan [177–179]. This provides an explanation for better response rates seen in patients treated with a combination of TNF-α and chemotherapeutic drugs.

T-cell-mediated immunity has also been proposed to be an important constituent of TNF-α's antitumor response. This is substantiated by the observation that T-cell deficient mice exhibited diminished antitumor effects when treated with TNF-α [175]. Also, development of T-cell-mediated immunity was observed in tumor-bearing mice treated with TNF-α [180]. Besides, in experimental animal models, TNF-α has been implicated to be an important effector molecule required for the cytotoxic ($CD8^+$) T-cell and NK cell-mediated killing of tumor cells [181–184].

In conclusion, either of the above-mentioned mechanisms, alone or in combination, might be responsible for antitumor effects seen with local administration of high doses of TNF-α. All this evidence for antitumor effects of TNF-α provided a rationale for the use of recombinant TNF-α in the treatment of cancers. In 1998, recombinant TNF-α was approved by the European Agency for the Evaluation of Medicinal Products (EMEA) for the regional treatment of limb-threatening, locally advanced soft tissue sarcoma (STS) and metastatic melanomas in an isolated limb perfusion (ILP) setting, to avoid amputation of the limb [185, 186]. The success of TNF-α therapy in these patients is based on the antitumor effects observed due to high concentrations of TNF-α reached locally during ILP. TNF-α, given in combination with melphalan, showed 70–90% complete response rates [187]. It became the first agent to be registered for the treatment of cancer that improved drug penetration in tumors and selectively destroyed angiogenic vessels as well [188]. However, with systemic administration of TNF-α, severe toxicity of this cytokine became the major impediment for its use in other types of tumors. At the same time, there came very strong support for the tumor-promoting effects of chronically produced endogenous TNF-α, which has been discussed in detail in the following sections, and laid a strong foundation for the use of anti-TNF-α therapy in cancer patients.

***Tumor-Promoting Factor—Evidence*** TNF-α is expressed in a range of human tumors. Both mRNA and protein levels are found to be upregulated in tumor and/or stromal cells in human ovarian, breast, prostate, bladder, colorectal cancer, leukemias, and lymphomas [189–193]. In ovarian cancer, TNFR-1 was found on tumor and stromal cells while TNFR-2 was found in the leukocyte infiltrate, suggesting a potential for both paracrine and autocrine signaling [189]. In many reports, high circulating levels of TNF-α and its soluble receptors are associated with poor prognosis and resistance to therapy [193–197]. Some of the experimental evidence for procancer activity of tumors in animal models has been listed in Table 2 [168].

TNF-α cluster contains many polymorphisms including microsatellites and single nucleotide polymorphisms (SNPs). To date, 14 SNPs, mostly in the 5′ promoter regulatory region of the TNF-α gene, and 6 microsatellites have been characterized [198]. Eleven of these SNPs are located within this regulatory region and might therefore influence the transcription rate of this gene. Since an endogenous TNF-α level is being directly correlated with tumor promotion, people naturally producing high levels of TNF-α, due to SNP affecting TNF-α synthesis, have been found to exhibit higher susceptibility as well as severity of certain malignancies. For instance, in a study of 273 lymphoma patients, TNF-308 polymorphism has been linked to high plasma levels of the cytokine at disease presentation [199]. Furthermore, people possessing at least two TNF/LT high producer alleles were found to be at a high risk factor for first-line treatment failure, shorter progression-free survival, and over-all survival [199] as well as increased risk of developing myeloma [200]. TNF-α 308.2 polymorphism has been found to be associated

with advanced hepatic fibrosis and higher risk for hepatocellular carcinoma [201]. SNPs in the promoter region of TNF-α have been linked to susceptibility to prostate cancer [202]. TNF-α microsatellite polymorphisms have also been associated with increased susceptibility to human cancers [203, 204].

### 2.3 Mechanisms of TNF-α in Cancer Promotion/Progression

Pro-inflammatory cytokine TNF-α plays a direct role in survival, growth, proliferation, differentiation, and movement of not only the tumor cells but also of other cells found in the tumor microenvironment. Additionally, it may influence the interaction of tumor cells with stromal cells as well as their interaction with the extracellular matrix. Potential mechanisms of the procancer actions of TNF-α are summarized in Table 3 [168].

TNF-α may have direct effects on tumor cells. Experimentally, it has been shown that exposure to TNF-α in vitro is capable of transforming the carcinogen-treated fibroblasts, which can then form tumors in nude mice [205]. The molecular mechanisms for this effect have not been clearly understood but might involve damage to the DNA via formation of ROS [206]. Another plausible explanation is that via inhibition of cytochrome p450 or glutathione *S*-transferase isoenzymes, oxidative stress can be generated, which may induce DNA damage tolerance, inhibition of protein synthesis, and high rates of carcinogen-induced mutation [207]. At the same time, TNF-α may also have effects on tumor stroma and orchestrate changes in tissue architecture, typical to that seen in inflammatory process associated with wound healing. For instance, they have been found to induce angiogenic factors [e.g., VEGF, basic fibroblast growth factor (bFGF), and IL-8] [208–211], key angiogenic enzyme-thymidine phosphorylase [212], endothelial integrin [176] MMPs (e.g., MMP-9, involved in metastasis) [213], and various chemokines (e.g., MCP-1) [214]. It can also stimulate collagen production in mouse and human fibroblasts [215, 216] and stimulate their growth [217]. All these changes further promote tumor cell growth, proliferation, invasion, and metastasis. Moreover, through activation of transcription factor NF-κB, TNF-α can lead to increased receptor expression of other cytokines that induce proliferation, such as IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-1β. Yet another report suggests that in renal cell cancer, von Hippel–Lindau (pVHL) tumor suppressor gene can lead to translational repression of TNF-α, thereby establishing a new genetic link between TNF-α and malignancy [218]. Thus, the mechanism of TNF-α in the promotion of cancer is still a hot area of research and is witnessing new developments every year.

### 2.4 TNF-α in Pathophysiology of Cachexia and Cancer

TNF-α has been implicated in the pathophysiology of cancer-associated cachexia and anorexia syndrome as well as many solid tumors and hematological malignancies. In this section, the role of TNF-α in the pathophysiology of cancer-associated cachexia, multiple myeloma (MM), myelodysplastic syndromes (MDS), and other malignancies has been elaborated and hence explains the use of anti-TNF-α in these conditions.

***Cancer-Associated Cachexia*** Patients with advanced cancer show progressive weight loss (up to 80%), which is mainly due to loss of fat and skeletal muscle. This complex metabolic state characterized by fatigue, weight loss, and loss of appetite (anorexia) is known as cachexia. Cachexia and associated anorexia is one of the significant factors in poor performance status and high mortality rates of cancer patients. It accounts for 20% of cancer deaths [219, 220].

TNF-α, along with other cytokines and growth-promoting factors released by tumor cells, is involved in the pathophysiology of cancer-associated cachexia and anorexia syndrome, and both peripheral and central mechanisms have been implicated [221]. The role of TNF-α and other cytokines in the progression of cachexia is summarized below:

1. Cancer patients undergo a characteristic acute phase response (APR)—a series of physiological and metabolic changes associated with elevated levels of acute phase proteins (APPs) such as fibrinogen, C-reactive protein (CRP), serum amyloid peptide (SAM), and the like. This response is similar to that seen in tissue injury, infection, or inflammation [222]. The presence of an APP clearly distinguishes tumor-related weight loss from simple starvation [223]. The magnitude of the APR and the proportionate rate of body-mass loss in patients with lung and gastrointestinal cancers has been associated with shortened survival in these patients [224]. It has been seen that the APR is not only activated but also modulated by cytokine, including TNF-α production [219].
2. Uncoupling proteins (UCPs)—1, 2, and 3—are a family of mitochondrial proteins that mediate proton leakage and decrease the coupling of respiration to ADP phosphorylation, resulting in the generation of heat instead of ATP. UCP expression levels have shown to be increased in cancer patients, especially UCP3 found on skeletal muscle [225, 226]. This might account for increased energy expenditure seen in cancer-associated cachexia. It has been seen in animal models that changes in UCP expression might be induced by cytokines. For instance, a single injection of TNF-α in rats resulted in a significant increase in UCP2 and UCP3 mRNA levels in skeletal muscle [227].
3. Cytokine-induced activation of NF-κB results in decreased muscle protein synthesis [90, 91]. Cytokines are also responsible for the reduction of MyoD protein, a transcription factor, which modulates signaling pathways involved in muscle development. TNF-α and IFN-γ act together to specifically inhibit the activation of mRNA for myosin heavy-chain synthesis [92].
4. Cancer patients with cachexia experience progressive erosion of skeletal muscle, resulting in asthenia. Ubiquitin-dependent proteolysis in skeletal muscle is considered to be the most important pathway for protein degradation in a catabolic disease such as cachexia [228–230]. TNF-α is thought to be involved in induction of proteolysis through the ubiqutin–proteosome proteolytic pathway [231, 232]. Muscle proteolysis yields amino acids and oligopeptides that are utilized for hepatic synthesis of APPs. The ubiquitin–proteosome system also indirectly modulates protein synthesis through degradation of IκB protein and subsequently activating NF-κB. Cytokine-mediated release of cortisol from the adrenal gland further propagates the activity of the ubiquitin–proteosome system [233].
5. Cancer-associated cachexia is also characterized by loss of body fat, which seems to arise from an increase in lipolysis and $\beta$ oxidation [234]. TNF-α has been associated with increased lipolysis, mainly through suppression of the lipoprotein cleaving enzyme LPL [235, 236]. Subsequent increase in very low-density lipoprotein (VLDL) synthesis and decreased LPL activity hinder triacylglycerol clearance and result in hypertriglyceridemia [237]. All these processes result in progressive weight loss [238].
6. Under normal conditions energy intake is controlled primarily in the hypothalamus by specific neuronal populations, which integrate peripheral blood-borne signals conveying information on energy and adiposity status [239]. However, consistent data seem to suggest that cancer anorexia is mediated by the inability of the hypothalamus to respond appropriately to peripheral signals, indicating an energy deficit. Cytokines, including TNF-α and IL-1, appear to mediate this "hypothalamic resistance," by hyperactivating anorexogenic neurons and suppressing prophagic neurons [240, 241]. There is an increased production of corticotrophin-releasing factor, a potent anorectic agent, and in concert with PGs, suppress the production of the orexigenic agent Neuropeptide Y (NPY) [242]. Cytokine-driven deregulation of the monoamine system contributes significantly to the modulation of these effects [220, 240].

Although TNF-α is definitely important for tissue catabolism, its importance in cancer-associated cachexia has not been conclusively established. This is because

the serum levels of these cytokines in humans have not been correlated with development of cachexia, and there have been some conflicting reports [243–245]. Nonetheless, many clinical trials are underway to treat the cancer-associated cachexia with anti-TNF-α therapy, and their positive outcomes will be able to provide irrefutable evidence regarding their importance in supportive care for cancer. The use of this therapy is also likely to yield improved response rates and prolonged survival of cancer patients.

***Myelodysplastic Syndromes (MDS)*** MDS is one of the most prevalent hematological malignancies, which include a heterogenous group of bone marrow disorders with a common denominator being the ineffective production of normal mature blood cells [246]. The patients diagnosed with MDS are at a high risk to develop acute myelogenous leukemia (AML) [247]. One of the paradoxical clinical settings seen in most patients with MDS is peripheral cytopenia with a cellular or hypercellular bone marrow [248]. However, the cells in bone marrow fall short of developing into terminally differentiated mature blood cells due to a failure of differentiation and increased cell death or apoptosis [249]. Although there is no direct evidence for intramedullary apoptosis, the foremost hypothesis today is that MDS results from accelerated apoptosis [250]. This increased apoptosis of hematopoietic cells seems to be due to increased signaling through the DR and mitochondrial pathway of caspase activation [251–253].

Proapoptotic cytokines like TNF-α are reported to be present at elevated levels in MDS bone marrow [254, 255] and can serve to trigger the apoptosis through the DR pathway as shown in Figure 3 [256–258]. This forms the rationale for the use of anti-TNF-α therapy in MDS patients with an ultimate goal to restore ineffective hematopoiesis caused by the accelerated apoptosis [259, 260]. However, a word of caution is always associated with antiapoptotic therapy in that it may also immortalize a malignant clone if apoptosis is a protective mechanism.

***Multiple Myeloma (MM)*** In MM, a tumor of postgerminal center bone marrow plasmablasts/plasma cells (normal mature B cells) forms and these malignant cells are almost exclusively confined to the bone marrow. The MM cells interact with the bone marrow microenvironment, and these interactions are mediated through direct cell–cell interactions via adhesion molecules and cytokines secreted by bone marrow and MM cells. MM is accompanied by the abnormal presence of paraprotein in serum and/or urine, decreased normal immunoglobulin (Ig) levels and lytic bone disease [261, 262]. Increased bone marrow microvessel density (MVD) and increased levels of proangiogenic molecules such as bFGF and VEGF, mediate the enhanced angiogenesis for tumor cell survival, and this provides the rationale for treatment with antiangiogenic drugs such as thalidomide.

Serum concentrations of TNF-α was found to be higher in patients with MM disease [263]. Especially, it was higher in patients with progressive MM disease compared to those with stable disease [264]. TNF-α plays a complex role in the pathogenesis of MM. TNF-α, along with other cytokines such as IL-6, insulin-like growth factor-1 (IGF-1), and VEGF, is found in the bone marrow microenvironment and mediates the growth and survival of MM cells [265]. Their growth-promoting effects are mediated through the RAS/RAF/MAPK kinase (MEK)/MAPK (mitogen-activated protein kinase) pathway while their survival effects or resistance to apoptosis is mediated through the phosphatidylinositol 3-kinase (PI3K)/Akt pathway [266]. The cytokine-mediated activation of antiapoptotic PI3K/Akt pathway is also responsible for resistance to conventional and novel therapies for MM, such as dexamethasone and thalidomide, which executes their pharmacological action by targeting the mechanisms leading to enhanced apoptosis of the tumor cells [262].

Through activation of NF-κB, TNF-α upregulates cell surface adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), on both MM cells and bone marrow stromal cells (BMSCs), which thereby increase the tumor cell BMSC binding [266]. The adhesion of MM cells to BMSCs further upregulates the transcription of cytokines (e.g., IL-6, VEGF) in BMSCs, which thereby promote growth, survival, and migration of tumor cells through autocrine and paracrine signaling [267–270]. It has also been shown that adhesion of MM cells to BMSCs confers protection against drug-induced apoptosis [271].

Thus, anti-TNF-α therapy, which will target not only the tumor cells but also its microenvironment, can prove to be an effective way to overcome the resistance to current therapies and, hence, serve as a promising treatment model to improve patient outcome in MM patients.

***Other Malignancies*** TNF-α has been demonstrated to be involved in the pathophysiology of many other hematologic malignancies, such as AML [272, 273], hairy cell leukemia (HCL) [274], chronic lymphocytic leukemia (CLL) [275, 276], and agnogenic myeloid metaplasia (AMM) [277–280]. Besides, drugs modulating TNF-α levels have proven effectiveness in a range of other tumors such as renal cell and prostate carcinoma, melanoma, glioma, Kaposi's sarcoma, and the like. Approaches inactivating or blocking TNF-α may

increase response rates and/or survival in patients with these malignancies.

## 3 ANTI-TNF-α THERAPY FOR CANCER

All the anti-TNF-α drugs that have been approved or are being currently investigated for use in cancer treatment are listed in Table 4, along with their actual or proposed structures and their mechanism of action.

### 3.1 Protein-Based Inhibitors

Protein-based inhibitors of TNF-α function include anti-TNF-α monoclonal antibodies (e.g., infliximab, CDP571, D2E7) and soluble TNF-α receptors (e.g., etanercept and lenercept). Infliximab and etanercept are the ones that are being intensively investigated for their potential in oncology. Currently these two drugs have an approval from the FDA for use in RA, Crohn's disease, ankylosing spondylitis, adult patients with chronic plaque arthritis, and ulcerative colitis. However, the potential for adverse effects associated with the use of these proteins-based inhibitors must be addressed carefully before they are approved for use in oncology. Patients taking infliximab have been reported to be at a high risk for opportunistic infections that may progress to serious diseases and even death. The most prevalent concern has been an increased incidence of re-exacerbation of latent TB [281, 282]. TB testing has been recommended for patients before and during the anti-TNF-α therapies. Studies with infliximab have also shown a potential risk for worsening congestive heart failure, and a dose >5 mg/kg is contraindicated in patients with moderate to severe heart failure. In addition, a potentially increased incidence of lymphoma has been observed in patients treated with the injectable TNF-α inhibitors, and this risk is thought to increase with disease severity [283–286]. Issues regarding their immunogenecity also need to be taken care of. Besides, there are problems regarding the use of antibodies as pharmaceuticals, as they need to be injected and are relatively expensive. Nonetheless, if they are effective enough, these therapies can be quite lucrative.

***Infliximab*** Infliximab (Remicade; Centocor/Schering-Plough/Tanabe Sieyaku) is a recombinant chimeric (human–mouse) IgG1κ monoclonal antibody comprising of a constant region from human and a variable region from mouse. It binds with high affinity (association constant $10^{10} M^{-1}$) and specificity, to both soluble and membrane-bound form of TNF-α and, hence, prevents it from binding to its receptors [287, 288]. In turn, all the biological responses mediated by TNF-α through its receptors are neutralized. Due to its ability to bind to transmembrane TNF-α, infliximab may cause lysis of the cells that produce TNF-α, such as macrophages and monocytes, and this depends on antibodies and complement [288].

Due to its ability to neutralize the actions of TNF-α and ameliorate the cachectic symptoms in tumor-bearing mice [289, 290], infliximab's potential is now being explored for treatment and prevention of cancer-associated cachexia in patients with advanced cancer disease. Preliminary studies evaluating the safety and pharmacokinetic profile of infliximab for the cancer-associated cachexia and anorexia have reported improved survival and prevention of any weight loss in cancer patients [291]. Currently, infliximab is in clinical trials for the treatment of cachectic symptoms and fatigue associated with cancer.

Anti-TNF-α therapy with infliximab has also been attempted in MDS [292–294]. Currently, infliximab is in phase II clinical trials for the treatment of MDS. In clinical studies, treatment with infliximab has shown a limited but significant activity and a favorable side effect profile. Patients taking infliximab showed improved hematopoietic response associated with decreased apoptosis and 50% reduction in abnormal metaphase [293]. A multilineage response was observed with sustained increase in neutrophil and platelet count and rise in hemoglobin concentration [293]. The most common side effects seen were thrombocytopenia (19%), neutropenia (27%), rash (5%), and facial swelling (5%) [294].

***Etanercept*** Etanercept (Enbrel; Amgen/Wyeth) is a soluble dimeric form of the TNFR-2, consisting of the extracelluar ligand-binding domain of the human TNFR-2 linked to the Fc portion of human IgG1. The Fc component of etanercept contains the CH2 domain, the CH3 domain, and hinge region but excludes the CH1 domain of IgG1. It is produced by recombinant DNA technology in a Chinese hamster ovary (CHO) mammalian cell expression system. It consists of 934 amino acids and has an apparent molecular weight of approximately 150 kDa [295]. Being dimeric, etanercept has a stronger affinity for TNF-α than the monomeric forms of the receptor. It acts as a competitive inhibitor and binds specifically to two molecules of free TNF-α in the circulation, consequently inhibiting the signaling cascades as well as biological effects of TNF-α mediated through its cell surface receptors. Unlike infliximab, etanercept forms less stable complexes with memTNF-α and monomeric TNF-α [296, 297]. As a result, cells expressing transmembrane TNF-α that bind etanercept are not lysed in vitro in the presence or absence of complement. Also, etanercept can bind to TNF-β as well

and prevents it from binding to cell surface TNFRs, rendering it biologically inactive [295].

Due to its ability to block TNF-α, efficacy and safety of etanercept in recurrent ovarian cancer [298], metastatic breast cancer [299], pancreatic adenocarcinoma (in combination with gemcitabine) [300], and various other solid tumors is being investigated. Etanercept has also been evaluated in the setting of hematological malignancies, such as MM [301], MDS [302], myelofibrosis [303], and refractory hematologic malignancies [304]. The use of etanercept as a single agent has shown improvement in the constitutional symptoms, but only in a limited number of patients. Infact, an increase in TNF-α plasma levels was seen in some of the MM patients during etanercept treatment, which was coupled with poor prognosis in these patients [301, 305]. However, etanercept administration was found to be safe and the proportion of patients who experienced toxicities was quite low. The most common adverse events seen were fatigue, fever, flulike syndrome, myalgia, injection site reactions, low titer antinuclear antibodies formation, minor infections, and abdominal cramps [304]. Moreover, in combination with other active biologic or cytotoxic therapeutic agents, such as thalidomide and azacitidine, it may improve the clinical outcome of patients with these diseases, and this approach is currently in clinical trials.

### 3.2 TNF-α Synthesis Inhibitors

#### *Immunomodulatory Drugs*

##### *Thalidomide*

HISTORY AND CURRENT STATUS Thalidomide (THALOMID; Celgene Corporation) was first introduced in 1956 as a drug to cure morning sickness in pregnant women. It was reported to have sedative, tranquilizing, and antiemetic effects. However, this culprit drug soon became a bane of human life when its teratogenic effects came light. Pregnant women taking this drug gave birth to babies with severe developmental deformities that included stunted limb development and other congenital defects of ear, heart, and internal organs [306]. Around 8000–12,000 "thalidomide babies" were born at that time, and this is one of the major drug-associated tragedies to date [307]. It was withdrawn in 1961, just to be reinvented in 1965, this time as an immunonodulatory and an anti-inflammatory drug for erythema nodosum leporosum (ENL)—a potential life-threatening inflammatory complication of lepromatous leprosy [308, 309]. Thalidomide was given FDA approval for the treatment of acute ENL in 1998, only after thorough investigations of its immunological effects [310]. Meanwhile, many studies demonstrated the efficacy of thalidomide in the treatment of autoimmune and inflammatory diseases. As the potent antiangiogenic effects of thalidomide were discovered [311], a huge number of studies began to investigate its role as an anticancer drug. Finally, in 2006, thalidomide in combination with dexamethasone got approved by the FDA for the treatment of patients with newly diagnosed MM. However, due to the potential risks of teratogenecity associated with thalidomide, it is approved for marketing only under a special restricted distribution program called "System for Thalidomide Education and Prescribing Safety (S.T.E.P.S.) initiated by the manufacturer of thalidomide (Celgene, Warren, NJ, USA). Under this program, only prescribers and pharmacists registered with the program are allowed to prescribe the product. The patients receiving the drug should also comply with the requirements of the S.T.E.P.S.

CLINICAL USES Thalidomide possesses immunomodulatory, anti-inflammatory and antiangiogenic properties. Currently, thalidomide has FDA approval for MM and ENL. However, a number of clinical interventions for other autoimmune and inflammatory disorders as well as some cancers are in progress, which will validate the use of thalidomide in a range of other diseases.

Thalidomide in combination with dexamethasone is indicated for the treatment of patients with newly diagnosed MM. Thalidomide treatment in MM patients leads to decreased MVD [312]. Treatment with thalidomide leads to a 25–33% response rate in patients with refractory MM [313] and significant response rates in patients at other stages of disease as well [314, 315]. Thalidomide given in combination with dexamethasone acts synergistically and gives even higher response rate of 60–70%, even when patients have been unresponsive to either agent alone [316, 317]. Thalidomide is capable of overcoming drug resistance of human MM cells to conventional therapy [318]. Efficacy of thalidomide, with or without a combination with steroids or other chemotherapeutic drugs, has been shown in patients with many other hematological and solid tumors, as summarized in Table 5 [319], and confirmatory studies for some of these cancers are in progress. In some patients with myelofibrosis or MDS the need for transfusions may reduce after thalidomide treatment.

Due to its ability to reduce TNF-α levels, thalidomide has been shown to relieve clinical symptoms of cachexia associated with cancer [320], TB [321], HIV [322], and ENL [310]. In HIV patients thalidomide can also relieve the cachexia symptoms, apthous ulcerations seen in advanced HIV infection, as well as Kaposi's sarcoma associated with HIV-AIDS [322–325].

**Figure 6** Structure of thalidomide enantiomers. (Adapted by permission from Elsevier Ltd. [331].)

In leprosy patients, thalidomide is indicated for the acute treatment as well as maintenance therapy for prevention and suppression of the cutaneous manifestations of moderate to severe ENL. But it cannot be given as monotherapy for such ENL treatment in the presence of moderate to severe neuritis.

Studies have demonstrated thalidomide's efficacy in many autoimmune and inflammatory disorders such as RA [326], cutaneous lesions of SLE [327], Bahcet's disease [328], chronic graft-versus-host disease associated with allogeneic bone marrow transplantation [329], and also in congestive heat failure [330].

CHEMISTRY AND STRUCTURE–ACTIVITY RELATIONSHIPS

Chemically, thalidomide is [2-(2, 6-dioxo-piperidine-3-yl)-iso-indole-1, 3-dione] or α-(*N*-phthalimido) glutarimide and has the empirical formula $C_{13}H_{10}N_2O_4$. It has a gram molecular weight of 258.2. The glutarimide moiety contains a single asymmetric center, as marked by a star in its structure shown in Table 4 and, therefore, may exist in either of two optically active forms designated *S*-(–) or *R*-(+) in Figure 6 [331]. Thalidomide is a racemic mixture containing equal amounts of the *S*-(–) and *R*-(+) enantiomers and, therefore, has a net optical rotation of zero. Segregation of activities occurs between the two enantiomeric forms of thalidomide. While, the *S*-(–) enantiomer is associated with the teratogenic effects, and potently inhibits the release of TNF-α from monocytes [332], the *R*-(+) enantiomer seems to be responsible for sedation and acts through sleep receptors in the forebrain [333]. The two isoforms rapidly interconvert under physiological conditions [334] and, hence, the purification of a safer *R*-(+) enantiomer did not prove quite useful to get rid of the teratogenic effects of thalidomide. Thalidomide is an off-white to white, odorless, crystalline powder that is soluble at 25°C in dimethyl sulfoxide. Because of its lipophilicity, it is only sparingly soluble in water and ethanol.

Thalidomide intrinsically possesses pharmacophores with a wide range of activities within its small molecular skeleton. This includes sedative/hypnotic, antimalarial, and immunomodulatory activity. It is assumed that glutarimide moiety is related to its sedative/hypnotic and antimalarial effects while the N-substituted phthalimide structure is related to its immunomodulaory activity [335]. Thalidomide exhibits moderate antiangiogenic activity (ca. 26% inhibition at 100 μ*M*). The structure of some of the thalidomide analogs is shown in Figure 7 [336]. The major metabolite: 5′-OH-thalidomide (5-HT) shows moderate activity compared to thalidomide. Pomalidomide (CC-4047), the 4-amino analog of thalidomide, is less active than thalidomide (ca. 21% inhibition at 100 μ*M*). However, replacing the electron-donating amino group at the 4-position with an electron-withdrawing nitro group in 4-NT, resulted in a more potent antiangiogenic activity than that of thalidomide (ca. 32% inhibition at 100 μ*M*). The removal of the decarbonyl group of pomalidomide resulted in a newer, more potent analog of thalidomide, lenalidomide (CC-5013) (ca. 32% inhibition at 100 μ*M*). Replacing the electron-donating amino group at the 4-position of CC-5013 in 4-NHT, with an electron-withdrawing nitro group, shows just the opposite effect of CC-4047 and results in decreased antiangiogenic activity as compared to CC-5013. Substitution of bulky alkyl groups at the 2- and 6-position of the phenylphthalimide ring (structures 7–17) results in a much more potent antiangiogenic activity. The specific feature required for the enhanced antiangiogenic activity of these analogs is 2,

6-diisopropylphenylphthalimide structure, and the removal of this bulky alkyl group results in no or little activity [336].

MECHANISM OF ACTION OF THALIDOMIDE AND IMMUNOMODULATORY DRUGS (IMiDs) IN MM PATIENTS Available data from in vitro studies and clinical trials suggest that the immunomodulatory effects of thalidomide can vary substantially under different conditions. The mechanism of action of thalidomide and IMiDs is not fully understood. Also, in vivo, thalidomide gets metabolized rapidly to produce a number of metabolites. It is not very clear whether thalidomide or one of its metabolite contributes specifically to its immunomodulatory activity. Potential mechanism of actions of thalidomide and IMiDs in MM patients are depicted in Figure 8 [337].

INHIBITION OF PRO-INFLAMMATORY CYTOKINES In 1991, it was discovered that thalidomide inhibits the synthesis of TNF-α by activated monocytes, and it is mainly due to destabilization of TNF-α's mRNA. Thalidomide may also inhibit TNF-α released by other cellular sources, such as microglia and Langerhans cells, activated by inflammatory stimuli [338, 339]. Additionally, it may also inhibit the synthesis of other pro-inflammatory cytokines or growth factors such as IL-6 [340], IL-12 [341], IFN-γ [342], and IGF-1 [343]. Since TNF-α level is found to be elevated in many types of cancers, anti-TNF-α activity of thalidomide is likely to be beneficial in the treatment of cancer patients.

**Figure 8** Potential mechanism of actions of thalidomide and IMiDs in MM patients. Solid arrows indicate proliferation and survival of MM cells or proliferation of endothelial cells and vessel formation or activation of immune cells, respectively. Dashed arrows indicate inhibition of these effects. (Adapted by permission from Nature Publishing Group [337].)

INHIBITION OF NF-κB ACTIVATION It has been proposed that thalidomide's inhibitory activity can be explained on account of TNF-α induced activation of NF-κB, as seen in endothelial, epithelial, and myeloid cells, as well as, T lymphocytes [344]. As mentioned previously, NF-κB activation mediates many downstream biological effects of TNF-α. Thalidomide prevents the degradation of IκB-α by inhibiting IKK-β [345]. IMiDs are capable of triggering caspase-8-mediated apoptosis [346], and this IMiD-induced apoptosis in MM cells is associated with downregulation of NF-κB's DNA-binding activity, as well as the reduced expression of NF-κB-dependent apoptosis inhibitory proteins, such as the cIAP-2 and FADD-like interleukin-1 beta-converting enzyme (FLICE) inhibitory protein (c-FLIP) [346]. Thus, the immunomodulatory activity of thalidomide and IMiDs is mediated in part by inhibition of NF-κB [347]. In a nut shell, all these effects leading to increased susceptibility to apoptosis and reduction of growth-promoting factors result in inhibition of tumor growth.

INHIBITION OF ANGIOGENESIS Inhibition of angiogenesis (formation of new blood vessels) is an important process for growth and metastasis of solid tumors and forms the major basis for thalidomide's use in cancer. Thalidomide was first shown to inhibit bFGF-mediated angiogenesis by D'Amato et al. in 1994 [311]. Since then a number of studies have tried to shed light on the mechanism by which thalidomide exerts its antiangiogenic activity, though none of them has been conclusively established. In general, the angiogenic activity of thalidomide has been explained based on its ability to downregulate the proangiogenic genes, including VEGF and bFGF in the bone marrow endothelial cells. Also, in one study it has been found that thalidomide decreases expression of VEGF receptors in vitro through modulation of ceramide (a family of membrane lipid molecules) [348]. An inverse correlation has been established between TNF-α concentration and antiangiogenic effect, and it has been postulated that suppression of TNF-α is the mechanism by which thalidomide exerts its antiangiogenic activity. Thalidomide significantly decreases the levels of other proangiogenic factors as well, such as IL-6.

Cyclooxyegenase (COX)-2 is highly expressed in various human cancers and is needed for angiogenesis in a rat corneal model [349]. Thalidomide has been found to inhibit LPS-mediated induction of COX-2 by destabilizing its mRNA [350]. Subsequently, COX-2-mediated biosynthesis of PGE2 also gets inhibited, which further contributes to thalidomide's antiangiogenic activity [331, 351]. Thalidomide can also decrease the density of TNF-α-induced ICAM-1, VCAM-1, and E-selectin on the endothelial cells. Direct inhibitory effect on proliferation of endothelial cells for angiogenesis has also been reported.

In the early 1970s, using a rabbit cornea micropocket assay, it was proposed that classic congenital defects (abnormal limb development) that are caused by thalidomide treatment were due to inhibition of blood vessel growth in the developing fetal limb [311]. One of the models proposes that teratogenic effects of thalidomide are observed due to its ability to intercalate into guanine-rich promoter regions of DNA [343]. Thalidomide, or a breakdown product of thalidomide, specifically binds to these glycoprotein (GC) promoter sites, decreasing transcription efficiency of the associated genes. A cumulative decrease interferes with normal angiogenesis, which results in truncation of the limb. Intercalation into G-rich promoter regions of DNA may explain why certain thalidomide analogs are not teratogenic while retaining their TNF-α activity. On the other hand, the tissue specificity of thalidomide and its antiangiogenic effect against only certain neoplasias may be explained by the fact that various developing tissues and neoplasias depend on different angiogenesis or vasculogenesis pathways, only some of which are thalidomide-sensitive [343]. However, this link between inhibition of angiogenesis and thalidomide's teratogenicity remains largely unproven. There are other groups that have subsequently demonstrated that thalidomide inhibits mesenchymal proliferation in the limb bud [352] and induces embryonic oxidative stress [353]. Also, there is a strong evidence suggesting that, in vivo, thalidomide-induced apoptosis causes tissue degradation during early embryonic development resulting in limb truncations and microphthalmia [354, 355].

T-CELL CO-STIMULATORY ACTION Immune response begins when an antigen, that is, an infectious particle or abnormal cell, is engulfed by specialized phagocytic cells, such as macrophages or dendritic cells. These phagocytic cells are more appropriately termed as antigen-presenting cells (APCs). Following uptake of antigen, the APCs migrate to the lymph node and oligopeptides from the digested antigen are loaded onto MHC class II molecules present on the surface of APCs. These oligopeptides, in association with MHC-II are then recognized by specific TCRs present on the surface of TH cells [356]. A second co-stimulatory signal is also provided to the naïve T cells, which facilitates their activation and the subsequent generation of antigen-specific effector response. As shown in Figure 9A, this co-stimulatory interaction occurs between members of the B7 family of proteins on antigen-presenting cells and the CD28 molecules expressed on the surface of T cells [78]. In 1998 it was shown that thalidomide and IMiDs are able to co-stimulate T cells that have been partially

**Figure 9** (A) Activation of naïve t-cells requires co-stimulation. (B) Thalidomide and IMiDs overcome the requirement for co-stimulation. (Adapted by permission from Nature Publishing Group [78].)

activated by the TCR and hence overcome the requirement for co-stimulatory interaction between B7 and CD28 proteins [357]. Its co-stimulatory activity is depicted in Figure 9B. Thalidomide seems to enhance TCR-mediated signaling both in the absence and presence of secondary signals mediated through B7 and CD28 molecules. Due to its co-stimulatory activity, it is proposed that thalidomide might act as an immunological adjuvant to enhance an otherwise ineffective immune response against tumor antigens [358, 359]. Additionally, thalidomide stimulates cytotoxic T-cell proliferation and induces secretion of IFN-γ and IL-2 (cytokines involved in cytotoxic immune response). It also triggers TH-2 mediated cytokine production while concomitantly inhibiting TH-1 mediated cytokine production, the net effect being greater stimulation of cellular immune response against tumor cells. Thalidomide and IMiDs also modulate NK cell activity against tumor cells.

Interestingly, T-cell co-stimulatory activity of thalidomide is in contrast to the TNF-α synthesis inhibitor activity that leads to decreased TNF-α level. This differential activity might help to explain the clinically diverse effects of thalidomide, which include beneficial activity in some autoimmune diseases that are associated with increased TH-1 cells and some cancers that are associated with lack of tumor-specific TH-1 cells [78]. An increase in TNF-α level is seen in HIV-seropositive individuals [360]. Therefore, the immunomodulatory effects of thalidomide cannot be simply classified as TNF-α inhibitor or T-cell co-stimulator, and the clinical response is likely to depend on the patient's disease state and immunological status.

PHARMACOKINETICS Thalidomide is currently available only as a 50-, 100-, and 200-mg capsule formulation (Thalomid, Celgene, Summit, NJ, USA) for oral administration. The mean time to peak plasma concentrations ($T_{max}$) of thalidomide ranges from 2.9 to 5.7 h, indicating that thalidomide is slowly absorbed from the gastrointestinal tract. Poor solubility of thalidomide in aqueous media is likely to hinder its rate of absorption. In human blood plasma, the geometric mean plasma protein binding was 55 and 66%, respectively, for (+)-(*R*)- and (−)-(*S*)-thalidomide. Oral administration of thalidomide also leads to high concentrations of the drug in cerebro-

spinal fluid (about 50% of the plasma concentrations) [361]. In HIV-seropositive adult male subjects receiving thalidomide 100 mg/day, thalidomide is detectable in the semen as well.

Presently, the exact metabolic route and fate of thalidomide is not known in humans. Thalidomide undergoes both, nonenzymatic (spontaneous) and enzymatic metabolism mediated by cytochrome P450 enzymes in the liver, though the extent of enzymatic metabolism is much less than the nonenzymatic metabolism [362].

Thalidomide is rapidly degraded by spontaneous hydrolysis in an aqueous medium at physiological pH [363]. The four amide bonds of thalidomide are targets for hydrolytic cleavage and at pH 7.4, 12 hydrolysis products are formed by splitting these bonds [364]. Between pH 6 to pH 7, only the phthalimide ring undergoes cleavage, whereas at pH 7 and above, the glutarimide ring also undergoes hydrolysis [365]. The rates of inversion and hydrolysis increases with pH in the interval 7.0–7.5 [366]. All of the known hydrolytic products of thalidomide have been shown to be largely inactive. Some of the hydrolytic products with intact phthalimido and glutarimide rings may further undergo enzymatic metabolism by CYP40 enzymes, though this has still not been confirmed [362].

The enzymatic hydrolysis of thalidomide has been a subject of extensive investigation over several years. Oxidized products of thalidomide have been identified and are a focus of much attention. Glucuronide conjugates of thalidomide were also recently identified in mouse urine, but not in humans so far [367]. Thalidomide metabolism by cytochrome P450 enzymes is depicted in Figure 10 [331].

Thalidomide shows species-specific metabolism that may account for its species-specific action [368]. This is substantiated by the observation that thalidomide's teratogenecity is seen in rabbits and other species, but not in mice [361]. An active metabolite, 5′-OH-thalidomide, generated by cytochrome P450 2C19 (CYP2C19) isozyme-mediated oxidation of thalidomide seems to be responsible for its antiangiogenic effect [369, 370] . However, whether this is true in humans as well is still unclear. Furthermore, CYP2C19, responsible for the generation of 5′-OH-thalidomide, shows genetic polymorphism and eight variant alleles that predict the poor metabolizer phenotype (*CYP2C19*2* to *CYP2C19*8*) [371]. Thus, it has been hypothesized that interindividual variation in CYP2C19 activity may affect the activity and toxicity profile of thalidomide and may also lead to potential interactions with other drugs metabolized by the same enzyme [372].

The mean half-life of elimination for thalidomide ranges from approximately 5 to 7 h following a single dose and is not altered upon multiple dosing. Thalidomide itself has a renal clearance of 1.15 mL/min with less than 0.7% of the dose excreted in the urine as unchanged drug.

DOSING REGIMEN IN MM PATIENTS Thalidomide is administered in combination with dexamethasone in 28-day treatment cycles. The dose of thalidomide is 200 mg administered orally once daily with water, preferably at bedtime and at least 1 h after the evening meal. The dose of dexamethasone is 40 mg daily administered orally on days 1–4, 9–12, and 17–20 every 28 days.

ADVERSE EFFECTS Thalidomide dose of 200 mg or less is generally well tolerated in patients and fewer side effects are observed. However, all patients taking more than 400 mg/day experience thalidomide-related toxicity. The adverse effects seen with thalidomide and IMiDs are listed in Table 6 [337]. The most common side effects are somnolence and constipation, and most serious ones are venous thromboembolic events, such as deep venous thrombosis and pulmonary embolus, and peripheral neuropathy. Thalidomide is usually administered at bedtime to minimize somnolence and fatigue [319]. The incidence of thrombosis after treatment with thalidomide ranges between 2 and 23% but is higher among patients who receive chemotherapy [373–376]. The mechanism of thrombosis is still unknown, though there is speculation that thalidomide might alter the interaction between cancer cells and coagulation factors, induce prothrombotic events, and activate platelets and vascular endothelial cells [377, 378].

Teratogenecity is one of the most serious side effects seen with even a single dose of thalidomide taken by pregnant women. Major human fetal abnormalities that have been documented with thalidomide administration include amelia (absence of limbs), phocomelia (short limbs), hypoplasticity of the bones, absence of bones, external ear abnormalities (including anotia, micro pinna, small or absent external auditory canals), facial palsy, eye abnormalities (anophthalmos, microphthalmos), and congenital heart defects. Alimentary tract, urinary tract, and genital malformations have also been observed. Death of the thalidomide baby occurs at or shortly after birth. To avoid any teratogenic effects of thalidomide, the use of thalidomide is absolutely contraindicated in pregnant females. Since thalidomide can be found in the semen of males, unprotected sex with male patients taking thalidomide is also forbidden. Breast feeding and blood donation are prohibited for patients taking thalidomide.

Thalidomide treatment has led to an unexpected rise of HIV viral load in HIV-seropositive patients. Plasma levels of HIV mRNA were found to be elevated [379]. Though the clinical significance of this finding is not very clear, it indeed calls for caution.

Management of thalidomide-related adverse effects is based on four principles: (i) dose adjustment or temporary interruption of the treatment; (ii) avoidance of agents that enhance the thalidomide-associated adverse effects; (iii) administration of agents or measures that relieve the adverse effects; and (iv) regular clinical and laboratory monitoring for prevention of toxicity. Frequent laboratory tests recommended before the start of and during thalidomide treatment include tests for pregnancy, to avoid any teratogenic effects, neutropenia, and HIV viral load.

DRUG INTERACTIONS Thalidomide has been reported to enhance the sedative activity of barbiturates, alcohol, chlorpromazine, and reserpine. Also, the medications known to be associated with peripheral neuropathy should be used with caution in patients receiving thalidomide.

CONTRAINDICATIONS Thalidomide is contraindicated in women of childbearing potential unless alternative therapies are considered inappropriate. The patient should accept the condition that she cannot become pregnant while on thalidomide therapy. Because thalidomide is present in the semen of patients receiving the drug, males receiving thalidomide must never have unprotected sex with women of childbearing potential, even if, he has undergone a successful vasectomy. Thalidomide is also contraindicated in patients who have demonstrated hypersensitivity to the drug and its components.

*Thalidomide Analogs* Due to the severe toxicity and risks associated with thalidomide, there was a need to synthesize compounds with increased immunological and anticancer properties, but devoid of its toxic effects. Thus, two major classes of compounds have been synthesized using the first-generation IMiD thalidomide as the lead compound [78]. These include class I or immunomodulatory drugs (IMiDs) and class II or selective cytokine inhibitory drug (SelCIDs) [380]. While the IMiDs® were more potent TNF-α inhibitors and modulate the immune system by different mechanisms, SelCIDs selectively inhibit phosphodiestrase 4 (PDE4) and indirectly modulate TNF-α levels.

IMMUNOMODULATORY DRUGS (IMIDS) The second-generation IMiDs were developed in the mid-1990s with a rationale to improve the inhibition of TNF-α [381, 382]. Accordingly, a series of 4-amino-phthaloyl thalidomide analogs were developed [383–385], which were found to be 50, 000 times more potent at inhibiting TNF-α than the parent compound in vitro. Out of the many second-generation IMiDs, lenalidomide (CC-5013, Revimid, Celgene, Warren, NJ, USA) and pomalidomide (CC-4047, Actimid, Celgene, Warren, NJ, USA) have taken a lead. While lenalidomide already has FDA approval, pomalidomide is in phase II clinical trials for solid tumors. Third-generation IMiDs are also being developed now and are in preclinical testing. The focus for the development of these newer generation compounds is to enhance their antiangiogenic and immunomodulatory activities [336, 386] and, thus, could potentially have greater anticancer activity.

Like thalidomide, the mechanism of action of IMiDs is unknowm and appears to be mediated through the similar molecular targets as mentioned for thalidomide. However, IMiDs have been reported to be more potent and less toxic analogs of thalidomide [78]. They do not have any effect on PDE4 levels. Most significantly, they are far more potent than thalidomide at co-stimulating T cells that have been partially activated via the TCR [387]. The potential of IMiDs in enhancing protective antitumor immunity might prove to be an effective adjuvant in anticancer vaccination regimen. This is supported by preclinical in vivo data since pomalidomide was demonstrated to enhance a partially effective cancer vaccine and enable the generation of a long-term protective antitumor responses [388].

*Lenalidomide* Lenalidomide (REVLIMID; Celgene Corporation) is a second-generation IMiD. It is found to be more potent than the parent compound thalidomide [386, 389]. Its chemical name is 3-(4-amino-1-oxo 1,3-dihydro-2*H*-isoindol-2-yl) piperidine-2,6-dione. It has a mechanism of anticancer action that is similar to thalidomide and other IMiDs. In 2005, it was approved by the FDA for the treatment of patients with transfusion-dependent anemia due to low- or intermediate-risk 5q MDS. 5q MDS is a type of MDS where a part of the longer arm (q) of chromosome 5 has been deleted. Patients with this type of MDS may have low red blood cell counts that require treatment with blood transfusions. In 2006, it also got approved, in combination with dexamethasone, for treatment of multiple myeloma patients who have received at least one prior therapy. Clinical trials for many other types of cancers and in combination with other anticancer drugs are in progress. Being a thalidomide analog, lenalidomide also carries the risk of teratogenicity and is accordingly contraindicated in female patients of childbearing potential. Like thalidomide, lenalidomide is also available only under a special restricted distribution program called REVASSIST. It has been shown in human in vitro metabolism studies and nonclinical studies that lenalidomide is neither metabolized by nor inhibits or induces the cytochrome P450 pathway, suggesting that lenalidomide is not likely to be the cause or subject to P450-based metabolic drug interactions in humans. The major adverse effects associated with lenalidomide treatment are myelosuppression, leading to neutropenia and thrombocytopenia, and deep vein thrombosis and pulmonary embolism.

SELECTIVE CYTOKINE INHIBITORY DRUGS (SELCIDS) SelCIDs selectively inhibit phosphodiesterase 4 (PDE4) and indirectly inhibit TNF-α. Normally, cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) are converted to AMP and GMP, respectively, through the action of PDE4. Inhibition of PDE4 allows cAMP/cGMP to be elevated within the cells and this result in activation of protein kinase A (PKA). Activation of PKA, through a phosphorylation cascade, prevents activation of transcription factor NF-κB and in turn prevents transcription of the gene-encoding TNF-α, thereby resulting in a decrease in TNF-α synthesis [382, 390].

PDE4 isoenzymes play a particularly important role in inflammatory and immunomodulatory cells and are the predominant PDE in inflammatory cells, including mast cells, neutrophils, basophils, eosinophils, T lymphocytes, macrophages, and structural cells such as sensory nerves and epithelial cells [391]. Accordingly, the most promising role of SelCIDs compounds appears to be as anti-inflammatory agents, and many PDE4-selective inhibitors have shown efficacy in a number of inflammatory models, including asthma and RA [392–395]. However, a number of these compounds have exhibited antiangiogenic activity independent of their immunomodulatory activity [386, 396]. Moreover, SelCIDs have exhibited a potent activity against a range of solid tumors [397]. Their antisolid tumor activity is shown to

be caspase-3-dependent with an associated downregulation of antiapoptotic bcl-2 protein [397]. In yet another study, their antimyeloma activity is thought to be mediated through two mechanisms, that is, inhibition of VEGF and IL-6 production by interacting myeloma and endothelium and induction of myeloma cell apoptosis [398].

A number of SelCIDs have been developed by Celgene Corporation and investigated for different types of cancers. One of the compounds, CC-8490, a benzopyranone, was found to inhibit the growth of glioma cells and induce glioma cell death in preclinical studies [399]. Recently, it has completed phase I clinical trials for progressive or recurrent malignant gliomas where the maximum dose of CC-8490 that can be given to patients and the safety and tolerability of this drug were assessed. Another compound, CC-1088, is also being studied as a potential treatment for MDS and leukemia and is in phaseI/II clinical trials. Thus, SelCIDs are yet another type of thalidomide analogs with a novel mechanism of action for anticancer therapy.

***p38 MAP Kinase Inhibitors*** Kinases are the phosphorylating enzymes that carry out ATP-dependent phosphorylation of serine, threonine, or tyrosine residues on regulatory and structural proteins and hence modulate various signal transduction cascades involving these proteins. The p38 MAPK is a serine/threonine kinase having four isoforms (α, β, γ, δ) and plays an important role in the cytokine production as well as in cytokine action. The production of various cytokines is regulated by p38 MAPK at both trancriptional and translational level. mRNAs for the inducible cytokines are short lived and, as mentioned previously, they contain ARE in their 3′ UTR, which is one of the major point of posttranscriptional regulation. Under normal conditions these AREs are occupied by ARE-BPs, which prevents their translation. In response to various stimuli such as LPS or environmental stress such as osmotic shock, UV light or certain growth factors, p38 MAPK gets activated through a series of phosphorylation events, as mentioned in Figure 11 [400]. As shown in Figure 12, once activated, p38 MAPK, via MAPK-activated protein kinase 2 (MAPKAP K2) phosphorylates the androgen binding proteins (ABPs), thereby releasing them from ARE on mRNAs [400]. The free mRNAs can now undergo translation. Furthermore, p38 MAPK, along with other MAPKs and Janus kinase (JAK)/signal transducers and activators of transcription (STATs) pathways, also phosphorylates a variety of transcription factors, such as NF-κB, which is responsible for transcriptional expression of pro-inflammatory cytokines such as TNF-α [400]. In addition to that, as shown in Figure 12, p38 MAPK pathway also gets activated in response to TNF-α binding to TNFR-2 and thereby mediates various downstream biological actions of TNF-α, which promote cancer cell survival.

**Figure 11** MAPK pathway. Mitogen-activated protein kinases (MAPKs), which integrate and process various extracellular signals. MAPK kinase (MAPKK or MEK), MAPKK kinase (MAPKKK), extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK). (Adapted by permission from Nature Publishing Group [400].)

p38 MAPK inhibitors block the action of p38 MAPK and, in turn, inhibit the action and biosynthesis of various pro-inflammatory cytokines such as IL-1, IL-6, IL-8, TNF-α, TGF-β, and IFN-γ. This forms the rationale for their use in anticancer therapy. These inhibitors are selective, competitive inhibitor of p38 MAPK and compete for the binding of ATP within a central binding pocket in the kinase enzyme. This central binding pocket is formed between α and β domains and is structurally conserved in all catalytically active kinases to

**Figure 12** Inhibition of TNF-α mRNA translation and transcription. Triangles indicate AREs, purple circles indicate ARE-BPs, red crosses indicate point of action of p38 MAPK inhibitor. (Adapted by permission from Nature Publishing Group [400].)

facilitate the transfer of γ phosphate from ATP to the substrate [401].

Various p38 MAPK inhibitors have been developed, such as AMG 548, BIRB 796, VX 702, VX 745, SCIO 469, SCIO 323, 681323, and RWJ67657, and many of them are being investigated for effectiveness in inflammatory, autoimmune, and malignant conditions [402]. SCIO-469, belonging to the Scios group of inhibitors, is of particular interest since it is at the most advanced stage in clinical testing and has shown efficacy in cancer. It was synthesized by Scios but now has been purchased by Johnson & Johnson, Inc. Its structure has not been released, but it is assumed that it is a piperazine indole oxalic acid analog as shown in Table 4 [403, 404]. Currently, it is in phase II clinical testing for RA [405], MM [406], and MDS [407]. In MM patients, SCIO-469 has been found to decrease proliferation of MM cells and block the IL-6 and VEGF secretion from BMSCs [408]. It also prevents TNF-α-induced adhesion of MM cells through ICAM-1- and VCAM-1-independent mechanisms [409]. Given in combination with a proteosome inhibitor, bortezomib, SCIO-469 has been shown to augment the cytotoxicity of bortezomib, in part due to downregulation of heat shock protein 27 (Hsp27), a molecule whose overexpression has been associated with resistance to dexamethasone [410]. It also enhances bortezomib-induced MM cell apoptosis by upregulating proapoptotic p53 and downregulating antiapoptotic Bcl-$X_L$ and Mcl-1. In murine models of MM, SCIO-469 has been shown to prevent the development of osteolytic bone disease, reduce tumor burden, and increase survival [411]. Besides, there is evidence that p38 MAPK is constitutively activated or phosphorylated in MDS bone marrows. Inhibition of p38 MAPK by SCIO-469 has been reported to decrease apoptosis in MDS $CD34^+$ progenitors and lead to dose-dependent increase in hematopoiesis [412]. Use of p38 MAPK inhibitors is advantageous since the p38 MAPK pathway is used by many cytokines that are implicated in the pathophysiology of MDS and MM. Thus, targeting this pathway may have wider clinical benefits than treatments targeting individual cytokines alone, such as anti-TNF-α

monoclonal antibodies. Although in developmental stages, p38 MAPK inhibition appears to be a promising approach for effective anticancer therapy.

***TACE Inhibitors*** TNF-α-converting enzyme (TACE/ADAM17/CD156q) is the enzyme responsible for cleavage of membrane-bound propeptide (pro-TNF-α of 26 kDa) to form a secreted, soluble, 51 kDa, homotrimeric cytokine (sTNF). It is also required for shedding of the extracellular domains of TNFR-2 from the surface of the cells [413]. TACE is a zinc-dependent metalloprotease enzyme and is a member of the a distintegrin and metalloprotease (ADAM) family. Along with many other MMPs, the ADAM family belongs to the metzincin superfamily [414]. MMPs are a group of 24 enzymes that degrade the extracellular matrix (ECM) and basement membrane and aid in tumor invasion and metastasis [415, 416].

TACE is a multidomain, type I transmembrane protein and its expression is largely constitutive [417]. Besides shedding of TNF-α and TNFR-2 extracellular domains, it is required for generating soluble forms of TGF-α [413], L-selectin [413], amyloid precursor protein [418], and many other proteins [419]. The domain structure of TACE, as show in Figure 13A, has a zinc-dependent catalytic domain and a disintegrin-cysteine-rich (Dis Cys-rich) sequence [417]. The prodomain contains a cysteine that interacts with the active-site zinc and gets displaced for the generation of an active enzyme [417]. The role of the disintegrin domain is still unknown. Only processed TACE appears on the cell surface [417, 420]. In the absence of cell activators, the surface pool of the enzyme is long-lived. However, prolonged exposure of cells to cell activators, such as phorbol esters, causes the internalization and degradation of TACE [420]. Cleavage action of TACE has been depicted in Figure 13B [417].

**Figure 13** (A) Domain structure of TACE. The notch signifies the active site. TM; transmembrane, cyto; cytoplasmic. (B) Cleavage action by TACE. (Adapted by permission from Elsevier Ltd. [417].)

A number of peptide-hydroxamates, containing a hydroxamic acid group that chelates zinc, are found to be potent inhibitors of TACE. However, these inhibitors are not specific to TACE inhibition and can inhibit other MMPs as well. One such synthetic broad-spectrum MMP inhibitor (MMPI), which hit the market, is Marimastat (BB-2516) developed by British Biotech Pharmaceuticals Ltd (Oxford, United Kingdom). It was the first MMPI to have entered the clinical trials in the field of oncology and since then has been widely tested in many cancer models [421–428]. The principal effect seen with Marimastat was to retard tumor growth and metastatic spread by inhibiting the degradation of the extracellular matrix by MMPs. However, Marimastat failed drastically in clinical trials for glioblastoma, pancreatic, gastric, breast, and ovarian cancers [429] either due to major side effects and/or no clinical improvement [430]. The main toxicity observed with Marimastat in clinical trials was dose-dependent musculoskeletal pain that could lead to contractures, particularly of the hand, if the treatment was continued [431].

It was initially thought that soluble TNF-α generated by cleavage of membrane-bound TNF-α is the only active form of this cytokine capable of eliciting biological responses. However, it later became clear that membrane-bound TNF-α could also assemble as homotrimeric ligand and produce biological effects through both TNFR-1 and TNFR-2, via direct cell-to-cell contact. In this current scenario, TACE inhibitors, which inhibit the production of sTNF-α by inhibiting TACE, and have no effect on memTNF-α action seems to be of limited therapeutic benefits. Moreover, all the TACE inhibitors that have been synthesized so far not only inhibit TACE but also other MMPs. MMPIs are likely to prove beneficial in cancer therapy but no major success has been achieved so far [432–434]. This is because of incomplete understanding of the role of MMPs in cancer. Also, the complex interactions between MMPIs, natural tissue inhibitors of MMPs, and other key activating factors have not been unraveled. MMPs such as ADAMs have been shown to have other important cellular functions, and inhibiting them might lead to unforeseen side effects with MMPIs. Further complication arises because 20–30 different MMP subtypes have now been identified and the function of one is

likely to be compensated by others [429]. Lastly, MMPIs are cytostatic drugs and were found to be ineffective against advanced or late-stage tumors, which were present in most patients. In conclusion, success of TACE inhibitors is quite skeptical at this point, but further understanding into it roles and mechanisms is likely to give some useful inights for its use in oncology.

### 3.3 Miscellaneous Approach

***NF-κB Inhibitors*** As mentioned in Section 1, the target genes for the NF-κB group of transcription factors include a huge number of inflammation-related genes that get activated in response to cytokines such as TNF-α and IL-1 [60]. Genes dependent on the activation of NF-κB include those encoding TNF-α, IL-1β, IL-6, IL-8, and IFN-γ, the adhesion molecules E-selectin, ICAM-1, and VCAM-1, the enzymes nitric oxide synthase and COX-2, MHC proteins, and viral proteins. NF-κB also induces the transcription of antiapoptotic proteins called the inhibitors of apoptosis [435]. Besides various cytokines, a number of chemotherapeutic drugs, such as irinotecan and doxorubicin, can also activate NF-κB. Due to its ability to activate the transcription of prosurvival genes, activation of NF-κB in tumors leads to a resistant phenotype of tumors to both TNF-α-mediated cytotoxicity and chemotherapies. Thus, inhibition of TNF-α-induced activation of NF-κB offers an attractive adjunct therapy for treating many types of cancers. NF-κB can be inhibited by many different approaches [347]. This includes:

1. Small molecules that can interfere with the binding of NF-κB to DNA and inhibit NF-κB-induced activation of transcription of several target genes.
2. Small molecules that can interfere with dimerization of NF-κB proteins.
3. Inhibitors of IκB degradation and NF-κB nuclear translocation [436]. This includes inhibitors of E3 ubiquitin ligases and the E2 ubiquitin-conjugating enzymes responsible for phosphorylation-dependent poly-ubiquitination of the IκBs and inhibitors of proteosomes responsible for degradation of phosphorylated, polyubiqutinated IκB. One such inhibitor, bortezomib (Velcade, Millenium), is a 26S proteosome inhibitor and prevents IκB degradation. It has been approved by the FDA for treatment in multiple myeloma and mantle cell lymphoma [437, 438].
4. Inhibitors of IKK activity. Several NSAIDs, such as aspirin and salicylates [439–441], sulindac and its analogs [442], and sulphasalazine and its metabolites [443] are capable of interfering with IKK-NF-κB system. Thalidomide and its analogs, IMiDs, are also capable of inhibiting IKK activity and hence interfering with NF-κB activation [345]. Besides these, development of several selective inhibitors of IKK is in progress and is likely to show exciting results in the coming years [347].

Besides synthetic compounds, a number of plant derivatives such as sesquiterpene lactones, capsaicin, and resiniferatoxin have also been shown to interfere with NF-κB activation [444, 445].

## 4 CONCLUSIONS AND FUTURE PROSPECTS

At present, the advent of multifaceted compounds stemming from a variety of painstaking mechanistic approaches clearly demonstrate that anti-TNF therapy for the treatment of cancer is definitely on the horizon. Current understanding of cancer biology makes it worthwhile to picture tumor growth with a much bigger perspective. Culprits involved in tumor progression are not only the aberrantly growing tumor cells but also many other normally growing cells of the body, which contribute in forming an environment conducive to tumor growth. Thus, tumor growth depends on intercommunication between various cell types present in the tumor stroma, and at biochemical level this interdependence is manifested by the exchange of various types of mitogenic and trophic factors. These factors are secreted not only by the tumor cells but also by inflammatory cells and other cells present in the tumor stroma. One such factor present at elevated levels in tumor stroma is TNF-α, which is not only the key mediator of inflammation but many strong evidences now implicate its role in tumor promotion as well.

TNF-α is a unique molecule with various diverse actions on its target cells. Depending on the receptor type activated in response to its secretion, as well as site and duration of secretion, TNF-α can lead to cell proliferation in some instances and cell death in others. Likewise, its role in cancer is also paradoxical, inducing destruction of blood vessels and cell-mediated killing of certain tumors, as well as acting as tumor promoter. However, strong evidence now conclusively implicates the role of TNF-α in tumor progression, besides being a key mediator of inflammation. Due to the presence of a huge number of inflammatory cells in the tumor stroma, inflammation and tumor progression are viewed as two intertwined processes, further supporting the role of pro-inflammatory cytokine, TNF-α, in tumor progression. Thus, TNF-α serves as molecular bridge between inflammation and cancer, and targeting TNF-α with

anti-TNF-α therapy, with the aim of inhibiting tumor growth, would indeed be a lucrative approach.

Direct involvement of TNF-α has been shown in the pathophysiology of cancer-associated cachexia and anorexia. Thus, anti-TNF-α therapy with protein-based inhibitors such as infliximab and etanercept, which selectively block TNF-α action, is likely to prove beneficial in the supportive care for cancer by improving appetite, slowing down weight loss, and increasing general well being of cancer patients. However, interactions of tumor cells with other cells types in the tumor stroma are increasingly heterotypic, involving a huge variety of cells, cytokines, growth factors, and a number of different MMPs. Targeting these different allies of tumor progression with nonselective inhibitors of TNF-α such as immunomodulatory drugs (thalidomide and its analogs), p38 MAPK inhibitors, TACE inhibitors, and NF-κB inhibitors, and combining them with other chemotherapeutic regimens, would be a preferential approach to inhibit tumor progression. This is all the more important in light of the fact that the function of one of these allies can be well compensated by yet another type of cytokine, growth factor, or MMP. In this situation, a multitargeted approach with chemotherapeutic drugs possessing several modes of action or combination of several chemotherapeutic drugs with varying modes of action is likely to prove highly effective in deterring tumor growth.

Cancer is a disease comprising heterogenous pathophysiologies and etiologies that differs with every cancer type. Anti-TNF-α therapy mainly targets the tumor stroma. However, tumor stroma of a cancer patient also differs with each cancer type and its respective pathophysiology. Thus, variations in response to anti-TNF-α therapy in cancer patients are likely to occur due to different tumor stroma and inflammatory profile of each patient. Furthermore, as we aim to target tumor inflammation mediators for antitumor therapies, the potential consequences of inhibiting these key players of immune system, which also participate in antitumor immune surveillance, should not be disregarded. Due to their ability to mediate immune system development as well as cytotoxicity of immune cells against tumor cells, they are indeed the integral components of the body's first-line defense against tumor development and form the basis for anticancer immunotherapy. Moreover, due to their pleiotropic nature, many other biological processes, not involving immune system but mediated by these inflammatory mediators, are also likely to be affected and thus accounting for a huge number of side effects seen with chemotherapeutic drugs inhibiting their action. Nonetheless, it will be an analysis of loss-to-benefit ratio for each cancer patient that will determine the success of anti-TNF-α therapy in the coming years.

A myriad of anti-TNF-α drugs are in developmental stages and in different stages of clinical trials. In the coming years, a better understanding of the tumor immunology and cell-signaling pathways is likely to precisely define the role of anti-TNF-α therapy in oncology. Also, the development of high-throughput screening (HTS) methods is likely to aid in the development of many more anti-TNF-α drugs for oncology. Thus, anti-TNF-α drugs are yet another addition to the mission for the achievement of the "complete cure of cancer."

List of Abbreviations

| | |
|---|---|
| ADAM | a distintegrin and metalloprotease |
| AGO | Argonaute |
| AIDS | acguired immuno deficiency syndrome |
| AML | Acute myelogenous leukemia |
| AMM | Agnogenic myeloid metaplasia |
| AP-1 | Activator protein-1 |
| APC | Antigen presenting cell |
| APP | Acute phase proteins |
| APR | Acute phase response |
| APRIL | A proliferation-inducing ligand |
| ARE | Adenine and uridine-rich elements |
| ARE-BP | ARE-binding protein |
| ATF | Activation transcription factor |
| BAFF | B-cell-activating factor |
| BAFFR | BAFF receptor |
| BCMA | B-cell maturation antigen |
| bFGF | Basic fibroblast growth factor |
| BMSC | Bone marrow stromal cell |
| cAMP | Cyclic adenosine monophosphate |
| CDE | Constitutive decay element |
| cDNA | complementary deoxyribonucleic acid |
| CD30L | CD30 ligand |
| CD40L | CD40 ligand |
| cGMP | Cyclic guanosine monophosphate |
| c-FLIP | Cellular-FLICE inhibitory protein |
| CHO | Chinese hamster ovary |
| cIAP | Cytoplasmic inhibitor of apoptosis protein |
| CLL | Chronic lymphocytic leukemia |
| CNS | Central nervous system |
| COX | Cyclooxyegenase |
| CRD | Cysteine-rich domain |

| | |
|---|---|
| CREB | Cyclic AMP-responsive element-binding protein |
| CRP | C-reactive protein |

## 1 INTRODUCTION

The use of medicinal drugs in pregnancy is not uncommon. Women during pregnancy are affected by the same illnesses as the nonpregnant female population of comparable age and socioeconomical status, as well as from multiple conditions that can arise from, or are worsened by, pregnancy. For example, some pregnant women suffer from medical conditions that require ongoing or episodic drug treatment such as asthma, epilepsy, or hypertension. Many of these conditions may require drug therapy, where withdrawal or a decrease of treatment can lead to a worsening of the underlying condition and, in other cases, to long-term complications or even death of either the mother or her fetus. Moreover, pregnancy can induce conditions such as nausea and vomiting that may need to be treated pharmacologically. Despite the dearth of data on safety and efficacy of most medications during this period, it has been estimated that as much as 60–80% of pregnant women in developed countries receive medications and most of them on more than one occasion [1].

While the woman's well-being is at the heart of any medical treatment, placental transfer of drugs leading to potential toxicity to the fetus is a major concern in the pharmacological management of the pregnant patient. This poses a dilemma to the health provider, who needs to weigh risks and benefits of drug treatment for the pregnant patient, including evaluation of the uncertainties produced by the little available data on fetal safety for most drugs. Hence, when managing a pregnant patient with medication, the exposure of two individual patients, mother and fetus, should be considered independently, and the decision must be based on the risk–benefit assessment of both.

While the use of prescription drugs can sometimes increase the risk of teratogenicity, some medical conditions such as gestational diabetes, hyperthyroidism, or hypertension may require drug therapy in order to ensure optimal health of the mother and fetus. In this setting, a small risk of fetotoxicity (or even a moderate one in certain circumstances such as previously transplanted patients who become pregnant) is offset by the large maternal benefits provided by the drug treatment.

Of the thousands of available drugs, relatively few have been clearly shown to have the potential to adversely affect the fetus when used at the recommended doses. For example, the use of most traditional anticonvulsants, while necessary for the treatment of the mother, may cause structural defects as well as impaired neurocognitive development in a small proportion of exposed babies [2, 3]. Thus, a potential maternal–fetal conflict brings to light the need to identify drugs that

**TABLE 1 Changes in Selected Physiological Parameters in Pregnancy**

| Physiology | Change in Pregnancy |
|---|---|
| Cardiac output | Increased |
| Tidal volume | Increased |
| Pulmonary blood flow | Increased |
| Gastric pH | Increased |
| Glomerular filtration rate | Increased |
| Renal drug elimination | Increased |
| Protein binding capacity | Decreased |
| Clearance | Increased |
| Total body water | Increased |
| Volume of distribution | Increased |
| Steady-state plasma concentration | Decreased |
| Peak serum concentration | Decreased |
| Intestinal motility | Decreased |

can effectively treat the mother without adversely affecting the fetus.

Placental passage of a drug, leading to fetal exposure, is a function of multiple factors such as protein binding, lipid solubility, pH difference between maternal and fetal fluids, ionization constant ($pK_a$), and the effect of hemodynamic changes in the mother during pregnancy, which govern maternal and fetal pharmacokinetics such as volume of distribution, rate of metabolism, and clearance by the placenta (Table 1). Ideally, one may wish to identify drugs that will not cross the placental barrier. However, with the exception of drugs with large molecular weights, such as heparin or insulin, most medications appear to cross the placenta and are associated with varying degrees of fetal exposure. Our objective is to present the state of relevant research and to stimulate interest in research efforts aimed at developing selective drugs for use in pregnancy. The hope is to explore therapeutic strategies that can either reduce unnecessary fetal exposure to drugs required by the mother or, in some instances, reduce maternal exposure to drugs destined for fetal treatment [4].

## 2 PLACENTAL PHYSIOLOGY

Typically discoid, the human placenta consists of the chorionic villi with attendant blood vessels and connective tissues [5]. Viewed from the maternal surface, the placenta has slightly raised areas denoted as maternal lobes or cotyledons. Each maternal cotyledon is associated with several fetal cotyledons, allowing for maternal circulation to be nearly superimposed on to fetal circulation. Considering the movement of materials from the mother to the fetus, molecules are carried by the maternal bloodstream in one of three ways: in free form dissolved in plasma, bound to carrier proteins, or bound to red blood cells. As a molecule crosses from the maternal to the fetal bloodstream, the solutes must cross the syncytiotrophoblast either by passing through the plasma membrane of the trophoblast or via a network of transporters (Fig. 1). Thus, transport across the placenta involves the movement of molecules among three compartments: the maternal blood, the cytoplasm of the syncytiotrophoblast, and the fetal blood. Solute levels in each of these compartments will play a key role in controlling the rate by which substances cross the placenta and are largely dependent on the initial absorption of the drug into the maternal bloodstream.

There is evidence for the presence of different cytochromes (CYPs), such as CYP1A1, CYP2E1, CYP3A4, CYP3A5, CYP3A7 and CYP4B1 at the messenger ribonucleic acid (mRNA) level, and protein and enzyme activity early in the first trimester of pregnancy [6]. Hokkola et al. [7] demonstrated that the mRNA but not the protein of several of the CYPs can be detected in term placenta, but levels were negligible in comparison to maternal liver. Furthermore, uridine glucuronosyltransferases (UGTs) (UGT1A, UG2B7, UGT2B11, UGT2B17, UGT2B11) increase the intrinsic clearance of several nonspecific substrates from 7.5 to 43% in full-term placenta as compared to liver. However, it is unlikely that the fetal or placental metabolism contribute significantly to the changes in CYP-catalyzed drug metabolism in pregnancy. For a listing of CYP expression in the placenta see Table 2 [8].

Furthermore, the trophoblast is the interface of exchange between the maternal and fetal circulations. As a barrier, the trophoblast has abundant expression of ABC transporters such as P-glycoprotein (P-GP) and multidrug resistance proteins 1, 2, and 3 (MRP1, MRP2, MRP3, respectively) (Table 3). Powered by adenosine triphosphate (ATP), these transporters actively extrude substrates from the placenta [9] (Table 3). Specifically, P-GP and MRP2 have been shown to be expressed on the brush border (maternal side) of the human placental trophoblast [10], while MRP1 and MRP3 are on the basal membrane (fetal side) [11,12]. Multidrug resistance transporters may result in lower cellular concentration of a drug via an efflux mechanism, thus creating pharmacological sanctuaries. For example, MRP1 and MRP3 preferentially transport organic anions, promote the excretion of glutathione and glucoronide metabolites, and thus attenuate their entry into fetal blood. P-GP is also an active drug transporter of the ATP-binding cassette transporter family with a wide range of substrates [11]. Abundant in the apical membrane of the placental trophoblast, P-GP transports its substrates in an outward (extracellular) direction. Since it can be detected in placental tropho-

blast from the first trimester of pregnancy [13], it is likely that it protects the fetus from amphipathic xenotoxins. Thus, fetal tolerance to maternal concentrations of drugs that are considered to be good P-GP substrates will be higher than that for drugs considered to be poor P-GP substrates. Then, it may be preferable to treat pregnant women with drugs that are good P-GP substrates, such as paclitaxel during antineoplastic chemotherapy in pregnancy, which may be preferred over other antineoplastic agents that cross the placenta more easily [14].

## 3 PHYSIOLOGICAL CHANGES IN PREGNANCY

During pregnancy, the maternal gastrointestinal absorption of drugs may be altered because of changes in gastric secretion and motility. Changes in gastric pH influence the degree of ionization and solubility of many drugs, modifying absorption rate and thereby altering drug bioavailability. Maternal drug metabolism may also be altered due to elevation of endogenous hormones such as progesterone. This can stimulate the hepatic microsomal oxidase system where elevated rates of hepatic metabolism may result in increased transformation of drugs such as phenytoin [2, 3]. Conversely, theophyline and caffeine exihibit a reduced hepatic elimination due to elevated levels of estradiol. In turn, estradiol inhibits microsomal drug metabolizing enzymes such as CYP1A2. Drug concentrations may also be affected by hemodynamic changes that take place throughout pregnancy. Cardiac output and blood volume increase up to 40%, primarily due to an increase in plasma volume [15]. Total body water also increases by 5–8%, due to the expansion of the extracellular fluid space and the growth of new tissue (placenta, mammary gland, the fetus) [2, 3]. Water also accumulates in the fetus, placenta and amniotic fluid, which collectively

contributes to an increase in volume of distribution and may lower the concentration of drugs and increase their elimination half-life (Table 4).

### 3.1 Protein Binding in Pregnancy

Protein binding alterations occur in pregnancy as a result of changes in the concentrations of specific proteins as well as changes in protein binding affinity for certain drugs. Decreases in maternal serum albumin may lead to corresponding increases in the free fraction of drugs [16, 17]. Increased levels of free fatty acids and total lipids together with gestational hormonal changes can also decrease the binding capacity of drugs to protein. This may have implications to maternal–fetal drug transfer, since binding changes may influence the maternal plasma concentration of free drug available to partition across the placental barrier. Furthermore, in late pregnancy there is a lower concentration of drug binding proteins and changes in binding affinity of drugs in the fetus: albumin concentration in the cord blood of neonates is markedly lower than the maternal levels [18]. In addition, there is a threefold lower level of $\alpha_1$-acid glycoprotein in the fetus compared to the mother [15]. Should free drug cross the placenta, the fetus will exhibit larger concentrations of free drug, due to diminished protein binding capacity.

### 3.2 pH Changes in Pregancy

Lipid solubility, the pH of the maternal and fetal fluids, the ionization constant of the drug ($pK_a$), and molecular weight all influence the passage of the drug across the placenta. In general, uncharged, un-ionized molecules with high lipid solubility and low molecular weight penetrate the cell membranes more readily than hydrophillic ionized drug molecules [19].

The transfer of weak acids and bases is influenced by the pH gradient between the maternal and fetal circulations and by the $pK_a$ of the drug. Since fetal plasma is slightly more acidic, 0.1 lower than maternal plasma pH, for weak bases, the un-ionized free drug crossing the placenta becomes ionized and is "trapped" in the more acidic fetal circulation [2, 18]. The pH of the amniotic fluid is also lower than that of maternal plasma. Therefore, the more acidic environment of both fetal blood and amniotic fluid favor ionization and accumulation of a basic drug due to "ion trapping," often resulting in fetal drug concentrations that may exceed maternal plasma concentrations and lead to toxicity.

Finally, at the placental cytoplasmic barrier, free drug can cross either by simple or facilitated diffusion or by active transport. Diffusion, simple or facilitated, depends upon the transmembrane concentration gradient, where it moves from a higher concentration compartment to an area of lower concentration. In contrast, active transport depends not only on solute concentration but also on a steady supply of ATP and progresses against a concentration gradient, potentially accumulating drugs in fetal circulation or, more commonly, pumping drugs back into the maternal circulation, against a higher drug concentration in maternal plasma. In addition, the placenta itself contributes to maternal–fetal drug transfer by possessing metabolizing enzymes capable of oxidation, reduction, hydrolysis, and conjugation, which can potentially convert an inactive drug into an active metabolite and vice versa. Clearly, the transfer of drugs across the placental membrane will vary, depending on the apparent volume of distribution, the degree of protein binding, acid–base equilibrium, metabolic and excretory mechanisms in the placenta and fetus, as well as hemodynamic alterations.

## 4 EXPERIMENTAL TECHNIQUES

Species differences in placental anatomy and physiology have precluded the generalizability of animal

**TABLE 5 Species Variation in Placental Physiology**

| Order | Placental Shape | Placental Type | Feto-maternal Integration | F/M Blood flow Interactions |

studies as they relate to humans [5] (Table 5). To circumvent these issues, techniques such as the dual perfusion of isolated human placental cotyledon have been well validated through transfer studies [8, 12, 20–26]. This technique is useful in the measurement of: (1) placental transfer of substances, (2) the effects of endogenous and exogenous substances on fetal pressure and transport, and (3) the release of endogenous substances into maternal and fetal compartments. The technique of in vitro perfusion of human placenta has been reviewed by Sastry [27] and Bourget [28].

### 4.1 Dually Perfused Isolated Human Placental Cotyledon

The technique consists of collecting human term placenta after delivery and immersing it in heparinized Krebs–Ringer bicarbonate buffer within 10 min of collection to remove any fetal blood components [29]. A single cotyledon, nourished by a single vein–artery pair without leaks, is isolated for perfusion studies. See Figure 2.

The placental cotyledon is perfused with 21% $O_2$, 5% $CO_2$. If necessary, in both the maternal and fetal circulating fluids (perfusate), albumin can also be added to mimic plasma. In this case, protein binding of the drug must be considered while measuring placental transfer [30]. Antipyrine is generally used as a freely diffusible marker to evaluate the placental transfer of drugs. Experiments can be performed using either the closed (recirculating) method or the open (single-pass or non-circulating) method [8] (Fig. 3).

In the closed model, both the maternal and fetal perfusates are recirculated. After a 1-h equilibration period, the drug and antipyrine (10 μg/mL, 53 μ*M*) are added to either the maternal and/or fetal reservoir and allowed to equilibrate for 3 h. Samples (1 mL) are taken from the maternal and fetal circuits at regular intervals (30 min) for the measurement of the drug, antipyrine, lactate production, and glucose consumption. The integrity and viability of placental tissue is ensured by monitoring the lack of fluid shifts, changes in partial pressures in both maternal and fetal circuits, lactate output, lactic dehydrogenase release, and glucose consumption [8].

Recirculating studies are not useful for calculating clearance data because these data change over time as more drug is transferred and accumulated toward equilibrium between the circuits [31]. Rather, we can calculate the percent transfer of drug, expressing the data as a ratio:

$$\%\ \text{transfer} = \frac{\text{Fetal concentration (at time } t)}{\text{Maternal concentration (at time } t)} \times 100$$

In open perfusion experiments, the fetal, the maternal, or both perfusates are not recirculated. In this context, a steady state can be attained. Maternal-to-fetal or fetal-to-maternal drug clearance (Cl) can be calculated by a standard formula [32], that is, maternal clearance:

$$\frac{[\ ]_{\text{fetal vein}} - [\ ]_{\text{fetal artery}}}{[\ ]_{\text{maternal artery}}} \times \text{fetal perfusion rate}$$

where [] is concentration.

**Figure 3** Schematic of a closed-circuit system used in the dually perfused isolated human placental cotyledon.

### 4.2 Trophoblastic Tissue

Human trophoblastic tissue preparations have been used to study the uptake into placental tissues, most classically used for amino acids and drugs uptake [33]. The assumption follows that what is taken up by the trophoblast would be transferred into fetal circulation by diffusion in vivo. The uptake is assumed to represent the transfer of substances from the maternal circulation into syncytiotrophoblast cells since there is no intact fetal placental circulation where the capillaries are usually collapsed [34]. Various types of preparations have been used for this type of pharmacological experiments; for example, placental slices, dissected syncytiotrophoblast tissue, microvillus membrane vesicles, and subcellular fractions such as microsomes have been shown to be good for drug metabolism studies [35].

### 4.3 Placental Tissue Slices

Placental slices have been found to be suitable for studying the effects of induction of transport systems relevant to fetal growth retardation [36]. Most often, they have been used to study amino acid uptake or transport using nonmetabolizable amino acids, such as α-aminobutyric acid (AIB) or as drugs of addiction. The sensitivity of this technique has been suggested to be the expression of compensatory responses such as the synthesis of new transporters and their incorporations into the plasma membrane. Amino acid transport has been suggested to be induced by preincubation [37]. This effect is seen in both term and preterm placenta. This behavior is characterized by the overall activity of these transporters being diminished in the early portion of the preincubation period due to an increase in membrane fluidity [38]. Practically, such compensatory mechanisms represent the possibility that the placenta may compensate in times of maternal starvation to synthesize new transporters or to increase their availability to spare the fetus from amino acid deprivation [39].

### 4.4 Syncytiotrophoblast Tissue

It is also possible to dissect only placental villi and to suspend them in physiological buffers, which also allows for the measurement of uptake of substances added to the medium [40]. In this preparation, the trophoblast surface is exposed to the medium. This preparation is used (1) to measure the uptake by the trophoblast from the suspension buffer of nutrients and drugs, (2) to measure the release of hormones, peptides, and biogenic amines from the trophoblast, and (3) to measure the effect of drugs and chemicals on these processes. Often, as with radiolabeled drugs, the uptake is measured as the inside/outside ratio [41]. This ratio assumes that all drug disappearing from the medium is taken up by the tissue. This assumption is valid only if uptake calculated by the above method is compared with the direct measurement of labeled drug (e.g., radiolabeled) in the placental tissue. The total drug measured directly in the placental tissue at the end of the experiment should be

the same as that calculated by the calculated method. During a 90-min incubation period, ratios of 7–10 are typically obtained and uptake often remains linear for up to 2 h, depending on the buffer medium [42].

This method has advantages compared to direct measurement of intracellular drug concentration in tissue. Because there is a significant variability among different pieces of the same placenta, by eliminating the removal of placental tissue to sample uptake, the same tissue remains in the medium throughout the experiment [43]. This technique allows for the same tissue to serve as its own control when uptake during the first half of the experiment is compared with uptake during the second half (i.e., should a second drug be added). This method is sufficiently sensitive to detect small drug-induced differences in uptake that cannot be observed by sampling the tissue directly [44]. Since the incubation medium is sampled instead of the tissue, more samples can be collected, more frequently.

### 4.5 Plasma Membrane Vesicles

Plasma membrane vesicles consist of exfoliated microvilli from the synciotrophoblast cells of human placenta [45]. The exfoliated microvilli are purified by differential centrifugation and washing. Essentially, plasma membrane forms microvesicles whose orientation is tested by two markers: alkaline phosphatase to test for brush border vesicles enrichment and $Na^2+/k$ + ATPase for basal lateral membrane enrichment [46]. This preparation is a more specific way of studying the effects of drugs on transporters or endogenous substances across specific placental plasma membranes [47].

### 4.6 Cultured Human Placental Villi and Cells

The human placental membrane contains several receptors as well as transporters (Fig. 1) [48, 49]. It is difficult to study receptor up/downregulation, sensitization/desensitization, and tolerance development in whole placenta. The availability of in vitro purified trophoblast systems allows for the study of several aspects of trophoblast functions, such as transport, secretion of steroids or hormones, and other systems in human placenta. Danels-McQueen et al. [50] have developed a method for isolating trophoblast from first-trimester placenta as well as recipes for culture media for their growth. Large multinucleated islands that represent differentiated forms of trophoblast are marked by their difference in human chorionic gonadotropin (hCG) and protein production. First-trimester placentas are favored over term placentas since they yield 40% more cytotrophoblast as compared to only 11% cytotrophoblast from term placentas.

Furthermore Hall et al. [51] have described a procedure for short-term tissue culture of human midterm and term placentas. From term placentas, monolayer cell cultures can be obtained that contain viable trophoblast cells. The optimal culture conditions occur with media containing epidermal growth factor (EGF), high-density lipoprotein (HDL), insulin, and transferrin. Hormone secretion is promoted in media containing 10% fetal calf serum (Dubelco's minimal essential medium, DMEM). Kliman et al. [52] improved on Hall's procedure by introducing a discontinuous Percoll density gradient to purify trophoblast cells. The cells prepared by this method become cultured aggregates and a "synctium" is formed that secretes hCG and human placental lactogeu (hPL) within 18 h and by 24 h.

### 4.7 Malignant Trophoblast Cell Culture

Three pure trophoblast cell lines derived from human gestational choriocarcinoma are presently available.

***BeWo Cells*** BeWo cells are a parabiotic combination of malignant gestation choriocarcinoma of the fetal placenta and human decidual tissue, which secrete a spectrum of placental hormones such as hCG, hPL, polypeptide hormone, estrogenic and progestational steroids, estrone, estradiol, and progesterone. Nevertheless, Takeuchi et al. [53] have shown that the molecular characteristics of BeWo hCG and its subunits, such as molecular weight, possible structure of sugar chains, are different from those found in normal placental cells.

These cells exist as two phenotypes in culture: the predominant form, 96–99% of the total population is cytotrophoblast-like (CTL), are proliferative and mononucleated; the remaining cells are syncytiotrophoblast-like (STL), nonproliferative and multinucleated. Furthermore, these cells are methotrexate (MX) [a deoxyribonucleic acid (DNA) synthesis inhibitor] resistant. This property is useful for the differentiation of BeWo cells. Methoxytrexate treatment causes inhibition of cell division but does not stop nuclear division of DNA or protein synthesis, yielding a population of giant multinucleated, nonproliferative cells that are morphologically indistinguishable from the naturally occurring STL cells. This effect is reversible upon withdrawal of methoxytrexate treatment. As such, the BeWo cell line is a valuable model culture system for investigating mammalian trophoblast development.

***JAr Cells*** JAr cells were established by R.A Pattillo [54] directly from a trophoblastic tumor of the placenta and is considered the preferred placental malignant cells model. This cell line produces estrogen, progester-

one, gonadotropin, and lactogen in culture. For a complete characterization of cellular morphology, hormone production, protein production, and enzyme compliment see [41].

Techniques have been developed to grow JAr cells as muticellular spheroids [50], which renders them the most suitable model for studying normal placental cell functions. A spheroid is a cultured suspension, and their growth is not limited by the size of their culturing environment. A spheroid culture system allows for the formation of a three-dimensional arrangement of cells that can be kept in culture for at least 3 weeks. These cells can grow as large as 1 mm in diameter, which can allow for the assessment of the contribution of cell density on treatment effect. The long culture period and free-floating three-dimensional nature of the spheroids is what mimics in vivo conditions. This is more advantageous than traditional monolayer cultures for the study of placental functions, which change with time, acute and chronic effects of drugs on trophoblast function, or for the study of higher placental functions such as implantation or differentiation, where the three-dimensional arrangement of the cells is desirable to observe.

***JEG-3 Cells*** JEB-3 cells are one of six clonally derived cell lines isolated and described by Kohler and Bridson [55]. They have been shown to release human chorionic gonadotropin, human chorionic somatomammotropin, and progesterone and transform steroid precursors to estrone and estradiol. Ringer et al. [56] have suggested that cyclic adenosine monophosphate (cAMP) regulates the expression of endrocrine functions of normal trophoblast cells in part by controlling the abundance of mRNAs encoding steroidogenic enzymes and hCG subunits. Several studies have used JEG-3 cells to investigate aspects of trophoblastic functions including the differential regulation of hormones, transcriptional regulation, stimulation of synthesis, and the release of hormones. JEG-3 is slowly proving to be an important model system for investigating the effects of drug and toxicants on cellular differentiation.

### 4.8 Animal Models

Although placentas of all species are similar in that the distance between maternal blood and fetal blood is decreased in later stages of gestation, the manner in which they do so is variable [57]. With the exception of the primate, the features of the intervening cells with regard to permeability, active transport, and even metabolic activity vary sufficiently that implication from one species should be extended only cautiously to another.

On the other hand, the macaque and human hemomonochorial chorioallantoic placentas are quite similar, with the principal variations originating in the mechanism of blastocyst implantation [58]. While the macaque blastocyst invades the luminal epithelium of the endometrium on day 9 of a 168-day pregnancy, the human blastocyst is believed to implant about 7–8 days after spontaneous ovulations. The process of trophoblast development is described in several reports [59, 60]. Overall, the placentas of the macaque and human are very similar physiologically except that the anchoring villi have longer cytotrophoblastic cell columns in the macqaque. In addition, the junction of the endometrium with fetal tissue at the basal plate is much more regular in the macaque than in the human. In reviewing comparative implantation, it should be noted that caution should be exercised in extrapolation of information about blastocyst implantation from one species to another. This is equally applicable to extrapolating information concerning placental transfer characteristic between different species.

## 5 DRUG DEVELOPMENT PROCESS

The drug development process includes two main stages: preclinical and clinical development. Preclinical testing is mainly concerned with the identification of a molecule as a potentially useful drug and its evaluation in different experimental settings, including animals. The clinical stage encompasses all the steps necessary to prove safety and efficacy of a drug in humans.

### 5.1 Preclinical Testing

After a potential new drug is identified, it must undergo a myriad of experimental tests to define its mechanism of action, receptors, binding characteristics, organ distribution in an animal model. Once detailed information for the molecule is obtained, further studies are usually conducted in animals to evaluate pharmacokinetics (absorption, distribution, metabolism, and excretion) of the drug, toxicity, efficacy, and effective drug doses that will serve as a basis for studies in humans. Toxicity evaluation is an important part of animal testing and provides important information on what should be expected in humans, although not all human side effects are predicted by animal studies, neither will all toxic effects observed in animals occur in humans.

In North America, the complete data from preclinical studies has to be submitted to the Food and Drug Administration (FDA) in an investigational new drug (IND) application in order to obtain authorization to proceed to clinical studies. Similar procedures are

followed in other regions such as the European Union, Japan, and Canada, with variations according to the particular legislation of each country.

### 5.2 Clinical Testing

Testing of new drugs in human subjects in the context of controlled experimental trials is an essential requisite before the widespread use of the drug for a certain disease in people. As a matter of fact, many drugs never succeed in passing the clinical testing stage, which can reveal aspects of the drug that were previously undisclosed by preclinical studies (e.g., a drug may produce toxicities that were not observed in animals).

Most drugs are studied in humans following a defined sequence, commonly referred to as phase I, phase II, and phase III clinical trials. Each phase addresses slightly different questions regarding safety and efficacy of the drug in humans, with subsequent phases enrolling progressively more subjects, from roughly a dozen in phase I trials to hundreds, or even thousands, in phase III. All human clinical studies are expected to be conducted taking in consideration the ethics principles outlined in the Declaration of Helsinki (www.wma.net), and following good clinical practices as outlined by the ICH (International Conference on Harmonization) guidelines (www.ich.org).

### 5.3 Phase I Studies

The initial studies in humans of a new drug are known as phase I studies. Most of these studies are carried out in a few (usually no more than a dozen) healthy volunteers in order to obtain information on how the drug behaves in humans, including pharmacokinetics (what the body does to the drug, that is, absorption, distribution, metabolism, and excretion) and pharmacodynamics (what the drug does to the body, that is, drug effects) data, and basic toxicology information (i.e., common side effects). In some particular scenarios, drugs are tested on patients from the start, usually due to the expected toxicity of these medications that would only be offset by the expected benefits that they would provide to patients. Examples of this situation can be found in phase I studies of drugs for cancer treatment, human immunodeficiency virus (HIV), and some neurological diseases.

### 5.4 Phase II Studies

Once, and if, a drug has successfully passed phase I, it is subsequently tested in phase II clinical trials. It is worth noting that most (9 out of 10) drugs never reach this stage, as most drugs tested in phase I trials are found to have unexpected toxicities, little absorption, interactions with other drugs, or other metabolism issues or other problems that would make the drug potentially dangerous, useless in humans, too difficult to develop or administer (or, sometimes, even difficult to commercialize).

In phase II, drugs are tested in selected groups of patients that have the condition for which the drug has been developed. These studies enroll more patients than the previous phase (usually more than a dozen, but hardly ever more than a hundred), and they are designed to provide information that will allow optimal selection of dosage for the next phase. Also, data on therapeutic efficacy of the medication is obtained, although efficacy can not be proven with such small numbers of patients. This phase also provides information on the common toxicity spectrum in the population of patients where the drug is going to be used, which may differ from the one observed in healthy subjects.

By the time a drug enters phase II studies, it is required (by the FDA) that animal studies are done on three different species (usually rats, mice, and rabbits) to evaluate potential reproductive toxicity and teratogenesis. These are the only tests throughout the development process that attempt to address the effects of the drug during pregnancy. However, as previously stated, not all human adverse effects can be inferred from animals studies. These studies have to be completed before authorization is given to market the drug.

### 5.5 Phase III Clinical Trials

In this last phase of clinical testing, drugs are studied in large clinical trials in populations of patients with the target condition. These trials need to prove efficacy of the drug in the target population before a drug can be marketed. Most of these trials are double-blind, randomized, placebo-controlled clinical trials enrolling hundreds to thousands of patients (sometimes more). These studies most commonly compare the efficacy of the drug against a placebo (placebo controlled) or sometimes the standard of treatment, if a treatment that is partially effective already exists for the condition. The drug is usually given to the patients without the patient or the doctor administering it knowing whether medication or placebo is being taken (double blind).

If phase III clinical trials successfully demonstrate that a new drug is effective and safe, the drug is poised for marketing. Only then can the regulatory agency grant permission to sell the drug to the general population for the indication studied in the phase III clinical trials.

### 5.6 Postmarketing Studies (Phase IV)

After a drug is on the market, pharmaceutical companies are required to collect data on safety. These monitoring efforts should continue while the drug is on the market and include surveillance of reproductive effects if the drug has the potential to be used in pregnant women. Many registries collect information on pregnancy outcomes in women exposed to medications. This is the main way that information on effects of drugs in pregnancy is obtained, as formal clinical trials rarely include pregnant women (or even women in reproductive age unless they provide negative pregnancy tests and commit to use adequate contraception during the study). Clinical trials carried out exclusively in pregnant women are almost nonexistent (rare exemptions will be provided below) and are frequently small and largely funded by and conducted in academic centers, instead of the pharmaceutical companies as is the rule in most other situations [61]

## 6 SELECTED CASES OF DRUGS DESIGNED FOR USE PARTICULARLY DURING PREGNANCY

Few drugs have been developed specifically for pregnancy. Nevertheless, there are certain pathologies that develop only during the course of gestation, usually as a consequence of the interplay between the mother and the fetus. In this case, drug development in pregnant patients is the only option, where ethical and logistical issues render the drug impossible to test in a nonpregnant population.

The following examples are used to exemplify the particular obstacles faced in their development.

### 6.1 Atosiban

Spontaneous preterm labor and delivery accounts for approximately one-third of all preterm births and is the predominant cause of perinatal mortality and morbidity [62]. Oxytocin acting via uterine oxytocin receptors plays a central role in mechanisms of uterine contraction in preterm labor [63]. Research on the pathophysiological mechanisms of preterm labor and the local production of oxytocin in fetal membranes and deciduas lead to the idea of blocking oxytocin receptors to prevent premature uterine contractility. Oxytocin stimulates both oxytocin and vasopressin V1a receptors in preterm pregnancy. There is a dramatic increase of oxytocin receptor in the pregnancy myometrium as gestation progresses [64]. In this regard, the increase in myometrial oxytocin receptor density without a corresponding increase in oxytocin plasma levels during the early stages of pregnancy allows for the assumption that the uterine hemostatic imbalance is the result of an increased affinity of oxytocin to its receptor [65]. As such, oxytocin is believed to be the main culprit in inducing contractility of myometrium in both term and preterm births. Consequently, the mainstay of treatment is to employ oxytocin receptor antagonist to delay preterm labor.

Atosiban is an oxytocin receptor antagonist that binds to vasopressin V1a as well as to the oxytocin receptors. Atosiban has been shown to be equally as potent as previously used therapies, such as β-2 receptor agonists, and safer for both mother and fetus. An in vitro study of the myometrium of 27 women was treated with oxytocin, then washed in atosiban, and then rechallenged with oxytocin [65]. This study clearly showed an antagonist action of atosiban on oxytocin-induced myometrial activity in a concentration-dependent manner.

Following in vitro evidence of pharmacological activity of atosiban against oxytocin-induced myometrial contractility, safety studies were carried out in animals and later in healthy (male) volunteers. These steps were necessary in order to obtain authorization to proceed to testing atosiban in other human populations. A case had to be made to the regulatory agencies such as the European Medicines Authority (EMA) (Europe) and the FDA (United States) that this drug could only be tested in phase II clinical trials in pregnant women undergoing premature delivery, given that there is no other population where this drug would be effective. This posed a dilemma, given that drugs are only tested on a limited number of subjects before reaching phase II, and it was impossible to rule out uncommon and serious adverse drug reactions at this stage. To make matters worse, the particular population of pregnant women implied a double risk for adverse effects, as not only the mother but also the fetus might be exposed to the medication, albeit for a short period, and at a less sensitive developmental stage than the first trimester.

Finally, a placebo-controlled trial with 501 patients was conducted and showed that atosiban provides a significantly better tocolytic effect at or beyond 28 weeks of pregnancy when compared to placebo [63]. Due to the adverse effect profile of other tocolytic agents employed to date, such as pulmonary edema, particularly with the β-sympathomimetics, the use of tocolytics in extreme premature labor is still not justified due to the severe neonatal consequences such as respiratory distress syndrome, fetal tachycardia, and hypoglycemia. Furthermore, previous tocolytics have been shown to cause increases in maternal pulse and blood pressure, lipolysis, and severe metabolic acidosis. Nevertheless, atosiban treatment seems warranted since it provides both the maximum therapeutic effectiveness

and safety for both the mother and her unborn child as compared to previously used nonspecific oxytocin receptor antagonists [63–65].

### 6.2 Glibenclamide (Glyburide)

In some cases, drugs already developed for indications in the nonpregnant population find an application in pregnancy-specific conditions. Diabetes mellitus is a disorder of glucose metabolism, generally classified as type 1 (insulin dependent) or type 2 (noninsulin dependent) diabetes, with a special class denoted gestational diabetes, defined as diabetes mellitus that is identified during pregnancy [65]. Gestational diabetes usually develops in or after the 24th week of gestation, mainly due to the effects of placental hormones on glucose metabolism in the mother. Failure to recognize and treat this condition may lead to unnecessary morbidity in some pregnancies (i.e., macrosomia, shoulder dystocia, neonatal complications) [66]. Standard management for gestational diabetes includes a diabetic diet and exercise; however, some cases require further medical treatment in order to achieve and maintain euglycemia. Perinatal morbidity has been shown to correlate to the mother's level of glycemic control [67], and several clinical trials have shown that strict glycemic control can reduce the rate of malformations and perinatal mortality in the pregnant diabetic population [68].

Drugs usually used for treatment of type II diabetes have potential in the treatment for gestational diabetes, but their use in pregnancy is accompanied by risks, uncertainties, and/or significant difficulties. Insulin, the most accepted pharmacological treatment to date [69–70], still presents a risk of transplacental transfer, and, more importantly, noncompliance due to the need of frequent injections in an otherwise normal healthy population of pregnant women who need to acquire the skills required for correct compliance and control of the treatment. On the other hand, sulfonylureas, oral alternatives to insulin for the treatment of type II diabetes mellitus, are a class of drugs that appear to act by inhibiting potassium efflux via ATP-dependent potassium channels in pancreatic β cells. This action leads to cellular depolarization and calcium-stimulated release of insulin in the pancreas. In other words, they enhance the release of endogenous insulin. However, sulfonylureas have a teratogenic potential, and it is recognized that they can cross the placental barrier and appear in the fetal circulation, increasing the risk of neonatal hyperinsulinemia/hypoglycemia. This led to the virtual banning of their use in the pregnant population [71].

Still, Glyburide (glibenclamide) is a second-generation sulfonylurea that has been shown not to cross the human placenta both in vitro in perfused human placenta studies, as well as in vivo, where it is likely effluxed from the fetal circulation to the mother [70]. On the basis of this data, and given the substantial discomfort associated with insulin use in the population of pregnant women with gestational diabetes, a randomized control trial of 404 pregnant women suffering from gestational diabetes was conducted by Langer et al. [2]. No detectable levels of glibenclamide were found in cord serum of infants following maternal administration. Many factors seem to play a role in the failure of glibenclamide to cross the human placenta, including its exceptionally high protein binding (99.8%), which allows for less than 0.2% of free drug to circulate and cross the placenta. Additionally, its short elimination half-life, made possible by its low volume of distribution (0.2 L/kg) and rapid clearance (1.3 mL/kg/min), may limit the amount of Glyburide available for exchange through the placental barrier before it is eliminated from systemic circulation. Simply put, glibenclamide has only a brief opportunity to cross the human placenta [69]. Moreover, factors such as transport of Glyburide by drug transporters, such as the ABC transporter family, may be facilitating its efflux from the fetal side back into the maternal circulation. The unique interplay of pharmacokinetic parameters, such as high protein binding and short elimination half-life, in combination with its affinity for the ABC transporter family, is suspected to prevent Glyburide from crossing the placentae, making it suitable for treatment in pregnancy.

### 6.3 Doxylamine (Diclectin)

Diclectin is an antiemetic medication that contains 10 mg doxylamine succinate, a common antihistamine with intrinsic antiemetic properties found in over-the-counter sleeping medication and 10 mg pyridoxine hydrochloride (vitamin $B_6$) [72]. Pyridoxine may have intrinsic antiemetic properties and also may be synergistic with the antinauseate property of antihistamines. Diclectin has been used since 1950 and is considered to be a safe treatment for nausea and vomiting associated with pregnancy. However, because of its removal from the market in 1983, there is a 20-year gap in clinical pharmacological and toxicological research both in studying pharmacokinetics/dynamics as well as maternal and fetal safety. A large number of cohorts and case control studies as well as two meta-analyses have clearly shown that pregnant women exposed to the doxylamine–pyridoxine combination do not have an increased risk of delivering infants with birth defects. Furthermore, the international Cochrane Collaboration has systematically reviewed randomized trials of Diclectin and concluded that it safely provides considerable relief for nausea and vomiting associated with pregnancy.

**TABLE 6 Pharmacokinetic Behavior of Selected anti-HIV Drugs in Pregnancy**

| Drug Class | Drug | Half-Life | Clearance | Protein Binding | Bioavailability | Placental Transfer |
|---|---|---|---|---|---|---|
| Nucleoside reverse transcriptase inhibitors | Zidovudine | No change (1.1 h) | Increases | <25% | 63% | Cross by diffusion |
| | Lamivudine | No change (6 h) | No change | 10–50% | 55% | Cross by diffusion |
| | Didanosine | No change (1.5 h) | Increases | | 45% | Cross by diffusion |
| | Stavudine | No change | | | 86% | Cross by diffusion |
| Nonnucleoside reverse transcriptase inhibitors | Nevirapine | Unchanged | Increased | 60% | 90% | Cross by diffusion |
| | Efavirenz | Neural tube defect : not recommended for use in pregnancy | | | | |
| | Delavirdire | | | | | |
| Protease inhibitors | Nelfinavir | Unchanged (3–5 h) | | 98% | | Not detectable in cord blood |
| | Lopinavir | Unchanged (5–6 h) | | 99% | | |
| | Amprenavir | Unchanged (6 h) | | 98% | | 6–8% of maternal [concentration] in cord blood |
| | Saquinavir | | | 98% | | Not detectable in cord blood |
| | Hydroxicarbamide: Not recommended in pregnancy | | | | | |

*Source*: Adapted from [49].

Although there are newer antiemetics with potentially better profiles of efficacy and maternal safety ($5H_3$ antagonist), the issue of fetal safety dictates the use of older drugs in which more data exist [73].

### 6.4 Selected Anti-HIV Drugs

In certain clinical situations, fetal exposure to a drug may be desirable in order to treat the unborn child. An important example is antiretroviral treatment of HIV-infected pregnant women. Data suggest that nucleoside reverse transcriptase inhibitors rapidly cross the placentae (Table 6). Cord blood concentrations of Zidovudine and Lamivudine tend to equal maternal concentrations at the time of delivery, whereas cord blood concentrations of didanosine and zalcitabine are approximately 50% that of maternal concentrations [74, 75]. Nonnucleotide reverse transcriptase inhibitors, such as nevirapine, have also been shown to cross the placenta [74, 76]. Several factors may account for their passage, including the drug's lower protein binding (60%), low molecular weights, and favorable degree of lipophilicity (log octanol/water coefficient 1.81) [77]. Also, the majority are placental transporter substrates. Hence, these drugs passively diffuse across the placenta and are administered in sufficient doses to cross the placenta and prevent maternal–fetal transmission of HIV during labor.

Conversely, protease inhibitors (PI) do not cross the human placenta to a clinically appreciable extent [78]. Nelfinavir, ritonavir, saquinavir, and lopinavir undergo incomplete transplacental transfer [79]. Low PI placental transfer can be attributed to high protein binding (98%), and several are substrates for placental P-GP transporter [9]. For example, saquinavir is a P-GP substrate with a high molecular weight (767 g/mol), high protein binding (98%), and a low partition coefficient (octanol/water 4.1 $\log_{10}$) that may contribute to the small amount that crosses the placenta [80]. Other protease inhibitors that follow similar placental kinetics include indinavir, ritonavir, lopinavir, and nelfinavir. P-GP's relative affinity to different PI drugs varies three- to fourfold [81]. Nelfinavir has become a commonly used protease inhibitor during pregnancy because of its tolerability and potency; however, it has also been demonstrated to exhibit a more rapid development of viral resistance and less durable suppression of viral replication leading to a greater likelihood of HIV transmission to the fetus. Saquinavir monotherapy is not adequate and often requires "boosting" with low-dose ritonavir. However, ritonavir is rarely used in pregnancy owing to its frequent and severe gastrointestinal adverse effects [78]. Only 5.3% of maternal plasma concentrations of ritonavir are detected in fetal cord blood. Ritonavir's well-documented interaction and perhaps inhibition-selected members of the ABC transporter family may account for its exclusion from the placenta [82]. However, ritonavir's inhibition of these transporters is disadvantageous since it gives rise to drug exclusions, altered bioavailability, and changes in drug

distribution resulting in a decreased efficacy of treatment with time. If certain PIs are effluxed by the placenta, and not reaching the fetus, future use of appropriate drug transporter inhibitors, such as valspodar for p-glycoprotein, may allow for greater concentrations in the fetal compartment and the prevention of maternal–fetal HIV transmission.

As the use of combination antiretroviral regimens becomes increasingly common among HIV-infected pregnant women and the rate of transmission decreases, the safety, toxicity, and teratogenicity of these agents becomes paramount. For example, a common toxicity with zidovudine is bone marrow suppression and decreases in hemoglobin in infants exposed to zidovudine at 3 weeks of age [83]. As a class, nucleoside reverse transcriptase inhibitors have been suggested to cause fetal hepatic microsomal damage in infants exposed perinatally [84]. Additionally, combination therapy has been suggested to trigger glucose intolerance. Zidovudine in combination with lamivudine and nelfinavir fosters a reduction in neonatal insulin similar to that observed in type I diabetes [83]. These data may indicate an early damaging effect on fetal pancreas such as inhibition of proinsulin conversion to insulin due to the activity of these protease inhibitors. Cumulative damaging effects on pancreatic β cells may culminate in the death of these cells and consequent insulinopenia followed by clinical diabetes.

## 7 FUTURE DIRECTION: ORPHAN DRUG STATUS

Because of the disincentive of small markets and high liability, pregnancy-specific problems that would benefit from pharmacologic intervention such as preterm birth, induction of labor, nausea, vomiting, and cholestasis during pregnancy are removed from the natural connection between basic science and industry that has resulted in the majority of the progress from which we benefit in modern medicine [85].

However, many of the factors limiting drug development for pregnant women could be addressed by a "pregnancy drug act" modeled on the Orphan Drug Act or Best Pharmaceuticals for Children Act [86].

The Orphan Drug Act was the first initiative to specifically target improvements in the number of treatments for rare diseases. Here, patient advocacy groups put pressure on the government to promulgate the Orphan Drug Act in 1983. This was the first significant step worldwide as it provided a range of benefits that would encourage manufacturers to develop drugs for populations suffering from rare diseases. It was, indeed, the Orphan Drug Act that facilitated the rapid introduction of several drugs HIV infection to the U.S. market. The act defined a rare disease as one that is present in less than 7.5 per 10,000 of the population. Some of the benefits offered to the pharmaceutical industry included a 50% federal tax credit for clinical research costs, exemption from the FDA registration fee, 7 years market exclusivity, protocol assistance, and congressional grants of approximately $20 million [87]. Data from the first 11 years of the act shows that over 600 products have been given orphan drug status. Of these, 110 were licensed and are currently used to treat 8 million patients. In contrast, only 10 orphan products were developed in the previous decade [88]. Beneficial treatments over recent years have been developed for rare diseases such as Gaucher's disease, cystic fibrosis, hemophilia, HIV/AIDS, multiple sclerosis, and Tourette's syndrome.

Pregnancy is not rare but, sadly, today, pregnant women are a therapeutically orphaned population. The study of drugs in pregnancy is critical for several reasons. First, pregnant women often need drugs to treat conditions that can endanger the life of the fetus or their own. These drugs cannot be used optimally without proper clinical studies that define the pharmacokinetic and pharmacodynamic characteristics in this population and allow physicians to minimize toxicity and maximize efficacy. Second, this is a special population exhibiting unique characteristics not shared by any other, namely, she who hosts a second human being that can be adversely affected by drugs she takes [89].

Hence, clinicians are in a bind. There is a clear need for drugs properly tested in pregnant women in order to use them safely, but they cannot be tested unless there is reassuring data about its safety during pregnancy. How can this cycle be broken?

Considering that more than half of all pregnancies are unplanned, capturing these pregnancies and possible inadvertent exposures to drugs and following them up to term can create large cohorts that teach us about fetal safety. Case control and cohort studies can be gathered to address fetal safety. This can provide a first review of the basic characteristics of drugs in the pregnant population. Useful information about teratogenicity, adverse effects in the mother, and perinatal risk can be obtained and weighted in order to decide whether it might be safe to conduct trials with a given drug. This can be partially addressed by pregnancy registries such as Organization of Teratology Information Specialists (OTIS) and Motherisk. Nevertheless, the numbers of pregnancies captured by these registries are a minute fraction of the actual amount of pregnancies exposed to medications.

Second, preliminary pharmacokinetic information can be extracted from population studies that can be useful as a foundation for further studies. For most drugs, there is a wealth of pharmacokinetic data from the nonpregnant population that can serve as a guide

for the design of future trials, especially if the different physiologic variables that can alter the pharmacokinetics of the drug in pregnancy are taken into account. Cord blood sampling can be performed on neonates whose mothers received the agent to be studied. Both cord blood and maternal levels can be established and collected in a centralized manner in order to derive population pharmacokinetics data [85–88]. Moreover, many women are prescribed by their physicians drugs they need in pregnancy, and there is no ethical hurdle in studying their pharmacokinetics. Indeed, it might be even said that not studying these cases would be unethical, as an experiment is actually taking place, albeit informally, when a patient is prescribed an inadequately studied drug. It is widely held as unethical to perform such experiments and not to record the information they yield. This information would be of enormous benefit to future users of the same drug.

Third, in vitro studies, such as placental perfusion studies, can provide very useful insights into the pharmacological properties of the drug, some aspects of its pharmacokinetics, and characteristics of its placental passage. As shown above, this has proven to be of great value in the case of Glyburide in gestational diabetes [3].

Fourth, ideally, drugs used during the second and third trimester should be studied with a design that allows the subject to serve as her own control (i.e., obtaining data serially during the second and third trimester and then during the postpartum period) [90]. The studies should take into account the physiological variations that occur in pregnant women in order to measure the differences in pharmacokinetic variables (i.e., changes in protein binding, distribution volume, metabolism, half-life, etc.) [90]. New drugs should not be commonly prescribed during the first trimester until proven safe to minimize teratogenic risks.

Finally, a comprehensive list of drugs potentially useful for pregnant women with parallel medical conditions that need to be better tested should be established in order to prioritize those that are potentially most effective and safe. This should emphasize pregnant population needs over industry needs to approve a particular drug. For example, in a perfect situation, antibiotics or antihypertensives would be a much higher priority to test in well-controlled large clinical trials than other medications that address more infrequent problems but are more commercially interesting.

As such, a pregnancy drug act mirroring the already approved Best Pharmaceuticals for Children Act that pushes clinical drug trials in children, or the more recently approved European legislation Medicines for Children, may encourage the pharmaceutical companies to develop drugs should they be awarded patent extensions and liability protection. Furthermore, industry would benefit from a complimentary approach that would have regulatory agencies working hand in hand with them on pregnancy-centered study designs. Without progress on the regulatory front, drugs such as atosiban and Glyburide will unlikely have a chance to fully prove themselves as effective treatments in pregnancy in North America.

## 8 CONCLUSION

Presently, despite a very short list of proven human teratogens, pregnant women are orphaned from the tremendous advances in therapeutics, putting at risk their health as well as the health of their unborn children. Unless society takes a rationale approach, by employing breakthrough methods and models in the study and development of drugs in pregnancy, some of which have been described here, women and their unborn children will continue to be the object of major injustice and exposed to unjustified risks.

## 1 HISTORICAL PERSPECTIVE

Schizophrenia is a devastating mental illness that affects approximately 1% of the world population. The disease is characterized by disordered thinking and behavior, with an equal prevalence in men and women. The symptoms of psychiatric disorder in patients with schizophrenia can be divided into two types, positive and negative. Positive symptoms include hallucinations, delusions, and thought disorder. Negative symptoms represent the loss of qualities normally present in healthy individuals, including diminished emotion, lack of interest, and depressive signs and symptoms. The course of schizophrenia is variable but is usually recurrent and chronic, often causing severe disability. Prior to 1923 only physical methods of treatment were available for schizophrenia in the United States, and in 1923 psychotherapy was introduced in the United States by a European psychiatrist named Adolph Meyers. Psychotherapy was the mainstay of treatment available to manage schizophrenia until the 1950s when chlorpromazine came into the picture serendipitously. The revelation that pharmacological agents can treat schizophrenia led to the explosive growth of psychopharmacology and transformed the "art" of treating mental illnesses to the "science" of modern psychiatry. Currently, there are several classes of antipsychotic drugs available to psychiatrists to treat schizophrenia. Recent studies have shown that taking antipsychotic medications consistently is crucial and necessary to manage the symptoms and to control the risks of relapse. This chapter reviews the history of antipsychotics starting with the birth of typical antipsychotics developed over a half century ago, the current newer safer atypical agents for treatment of schizophrenia, and novel emerging therapies being developed in the new millennium.

## 2 DEVELOPMENT OF PHARMACOTHERAPY OF SCHIZOPHRENIA

### 2.1 Birth of (Typical) Antipsychotics

The discovery in the 1950s that chlorpromazine could effectively be used to treat schizophrenia was serendipitous. The drug, 4560 RP, later known as chlorpromazine (CPZ), was synthesized in 1950 by Paul Charpentier, a chemist at Laboratoires Rhône-Poulenc in France. Chlorpromazine is chemically a phenothiazine derivative with the IUPAC name 3-(2-chloro-10*H*-phenothiazin-10-yl)-*N*,*N*-dimethyl-propan-1-amine (Fig. 1).

It was designed and synthesized as a medication to reduce agitation or anxiety in patients before surgery. It was the observational ability and curiosity of a French surgeon Henri Labroit that brought to light the magical powers of chlorpromazine in treating schizophrenia. In 1952, with the help of some skeptical psychiatrist colleagues, Labroit tested chlorpromazine in a 24-year-old man who had mania. The medication made the patient calm for several hours with his eyes shut (although his facial expression still looked rather maniacal). Within 3

**Figure 1** Structure of chlorpromazine.

weeks he had largely calm and was even able to play bridge [1]. This was followed by several clinical trials in larger patient populations in several countries. Clinically, chlorpromazine significantly decreased positive symptoms in psychotic patients. By 1954 chlorpromazine became popular in Canada, the United Kingdom, and the United States. By 1956, the reduction in the number of inmates in asylums in the United Kingdom fell significantly, and pharmaceutical companies started coming up with several antidepressants and antipsychotics in the next few years. The realization of the clinical efficacy of chlorpromazine in schizophrenia marked the beginning of the golden age of psychopharmacology and psychiatry as a medical science. The treatment of mental disorders started to be based on symptoms, and the science of modern psychiatry began to evolve. The discovery of antipsychotics is sometimes compared to the discovery of penicillin for infectious diseases, anticonvulsants for epilepsy, or antihypertensive drugs for cardiovascular disease. The antipsychotic drugs soon became the cornerstone in the pharmacopoeia for the treatment of psychiatric illnesses. The antipsychotic drugs of this era are called "typical" antipsychotic drugs. However, because of their side effect profiles and substantial limitations, the optimism gradually faded about these drugs—typified by chlorpromazine, a low-potency medication; perphenazine, a drug of intermediate potency; and haloperidol and fluphenazine, high-potency agents. Following chlorpromazine, a number of different compounds were developed called the neuroleptics or typical antipsychotics. The term *neuroleptics* refers to the neurological, motor, or extrapyramidal side effects of these initial antipsychotic drugs [2]. Before the euphoria of the new discovery subsided, clinicians began to realize the troubling side effects of first-generation or typical antipsychotics exemplified by CPZ (Table 1).

Typical antipsychotics have been widely used and shown to be effective in the treatment of positive symptoms of schizophrenia and related psychoses, as well as in preventing psychotic relapses [3]. Typical antipsychotics are broken down into low-potency and high-potency classifications. Low-potency typical antipsychotics, such as chlorpromazine, thioridazine, and mesoridazine, have less extrapyramidal syndrome (EPS) side effects and more muscarinic (dry mouth), α-adrenergic (orthostasis), and histaminic (sedation, weight gain) side effects. In contrast, high-potency typical antipsychotics, including fluphenazine, haloperidol, molindone, thiothixene, trifluoperazine, loxapine, perphenazine, and pimozide, have more EPS side effects and less histaminic, α-adrenergic, or muscarinic side effects.

**TABLE 1 Currently Used Typical (First-Generation) Antipsychotic Agents**

| Low Potency Generic (Brand) | High Potency Generic (Brand) |
|---|---|
| Chlorpromazine (Thorazine) | Perphenazine (Trilafon) |
| Thioridazine (Mellaril) | Trifluoperazine (Stelazine) |
| Mesoridazine (Serentil) | Fluphenazine (Prolixin) |
| | Thiothixene (Navane) |
| | Haloperidol (Haldol) |
| | Molindone (Moban) |
| | Loxapine (Loxitane) |
| | Pimozide (Orap®) |

**Figure 2** Frequency of antipsychotic-induced parkinsonism with typical antipsychotics. (Data from PJ Weiden. *DSM_IV*, Vol. 1. APA Press; 1994.)

After the serendipitous discovery of the antipsychotic effects of CPZ, it was found that CPZ, as well as the other typical antipsychotics, improved the positive symptoms in psychotic patients by blocking dopamine receptors in the brain. Another observation that supports the dopamine hypothesis is the development of paranoid schizophrenia in patients with high doses of amphetamine, a drug that causes excess release of dopamine in the brain. This led to the concept that psychosis is caused by increased levels of dopamine and its activity, and most antipsychotic drugs block postsynaptic dopamine receptors [4].

The two most common unfavorable side effects precipitated from the treatments with typical antipsychotics are EPS and prolactemia [2, 5]. Extrapyramidal symptoms include pseudoparkinsonism, dystonia, akathisia, and tardive dyskinesia (Fig. 2). Dopamine is

**TABLE 2 Atypical Antipsychotics (Second-Generation Antipsychotics)**

| Generic (Brand) |
|---|
| Aripiprazole (Abilify) |

| Olanzapine (Zyprexa) |
| Quetiapine (Seroquel) |
| Risperidone (Risperdal) |
| Ziprasidone (Geodon) |
| Paliperidone (Invega) |

involved in several functions (emotion, motor activity, cognition) and also helps to regulate the release of prolactin. Thus blockage of $D_2$ receptors may treat positive symptoms (mesolimbic pathway) but may cause EPS (nigrostraital pathway) and increase of prolactin level (tuberoinfundibular pathway) [5].

The discovery of conventional antipsychotics has marked a major turning point in the history of psychiatry. While drugs in this class were effective in treating and preventing the positive symptoms in individuals with schizophrenia or related psychosis, the negative symptoms and cognitive deficits of the disease in fact worsened.

### 2.2 Development of Atypical Antipsychotics

The absence of an effect of typical antipsychotics on the negative symptoms and the severity of their adverse effects prompted the development of second generation antipsychotics that became known as "atypical" antipsychotics (Table 2). The introduction of atypical antipsychotics (AAs) marked a dramatic change and novel approaches in psychiatric pharmacotherapy. Clozapine was the first medication in this class, which was introduced and approved in the early 1990s for the treatment of psychotic conditions in individuals with schizophrenia. The term *atypical* describes their different dominant characteristics compared to "typical" or "conventional" antipsychotics. The AAs appear to cause far fewer EPS (pseudoparkinsonism and dystonia) and the absence or minimum effect of prolactinemia after being administered chronically, and yet they have the efficient in controlling positive symptoms [6].

Clozapine was developed in 1959 by a Swiss drug company and introduced in some European countries in 1971 and 1972 [6]. It took over 10 years for clozapine to gain its clinical reputation in the European market. The drug was later halted abruptly in 1974 when a rare but potentially fatal hematological (agranulocytosis) side effect was detected in treated patients. Fifteen years later, clozapine was approved by the Food and Drug Administration (FDA) in 1990 for use in the United States, after a large controlled clinical study had demonstrated the superiority of clozapine over conventional antipsychotic drugs. Clozapine has a number of characteristics that make it unique. It is significantly more effective in both positive and negative symptoms of schizophrenia. These days clozapine is only used for the treatment of resistant schizophrenia when at least two atypical antipsychotics failed to act on the patient [3]. The binding of clozapine at $D_2$ receptors is weak compared with conventional agents, and this characteristic may explain the absence of EPS. Other common side effects of clozapine are weight gain and strong sedation, which probably related to the blockage of 5-$HT_{2c}$ (serotonin), adrenergic $\alpha_1$, and $H_1$ receptors. Another common serious side effect is seizures, which occur in 5–10% of patients treated with doses above 500 mg [7].

Since the introduction of clozapine, several other antipsychotics have been approved by the FDA, carrying the descriptive label of "atypical antipsychotic." During the 1990s, olanzapine, risperidone, and quetiapine were introduced, with ziprasidone and aripiprazole following in the early 2000s. The newest atypical antipsychotic, paliperidone, was approved by the FDA in late 2006 [8].

Besides minimal or negligible EPS, all AAs have also been found to be effective in improving negative symptoms and cognitive dysfunction of schizophrenia. Studies showed that patients have experienced an "awakening" state, characterized by a return to a near normal level of cognitive, interpersonal, and vocational functioning and not just significant improvement in positive symptoms as observed with typical antipsychotic agents.

Serotonin-dopamine antagonism, selective $D_2/D_3$, or transient $D_2$ antagonism are key features for clinical actions of atypical agents [9, 10]. More details about the receptor's mechanism of action of atypical agents will be discussed throughout the chapter.

Atypical antipsychotics demonstrate an important advance in the treatment of schizophrenia [9]. Although associated with significantly less extrapyramidal motor side effects (EPS), negligible elevation of prolactin, and efficacy in both negative and positive symptoms [11], the metabolic side effects that have been of most concern to clinicians, patients, and the FDA are excessive weight gain, hyperglycemia, hyperlipidemia, as they may induce type II diabetes and heart disease in susceptible individuals [12, 13]. However, there are differences in their individual side effect profiles that should be taken into account when selecting a treatment. For instance, studies have shown that clozapine and olanzapine can cause significant weight gain and that risperidone may cause reproductive or hormonal side effects (prolactinemia) (Table 3).

Based on clinical experience, ziprasidone and aripiprazole produced less or no effects on metabolism compared to other AAs. This may be explained through partial agonism of $D_{2/3}$ and 5-$HT_{1A}$ receptors of aripiprazole, and high 5-$HT_{2A}/D_2$ receptor binding ratio of ziprasidone [15, 16].

## 3 NEUROPHARMACOLOGY OF ANTIPSYCHOTIC DRUGS

### 3.1 Dopamine Pathways and Dopamine Hypothesis of Schizophrenia

Although the hypotheses on schizophrenia have progressed beyond the dopamine hypothesis, the dopamine hypothesis is still prominent when describing the etiology of schizophrenia. There is a lot of anecdotal evidence for the involvement of brain dopamine in schizophrenia such as manic behavior in people consuming drugs that elevate brain dopamine levels (amphetamine, cocaine). Importantly, the majority of antipsychotic drugs are antagonists at dopamine receptors. Thus, there is no doubt that dopamine and dopaminergic pathways in the brain are involved in the pathophysiology of schizophrenia.

**TABLE 3 Comparison of Weight Gain after 10 Weeks of Antipsychotic Treatment**

| Drug | Mean Weight Gain (lb) |
|---|---|
| Ziprasidone | 0.09 |
| Haloperidol | 1.1 |
| Aripiprazole | 1.6 |
| Risperidone | 4.4 |
| Chlorpromazine | 4.7 |
| Olanzapine | 7.8 |
| Thioridazine | 7.8 |
| Clozapine | 8.9 |

*Source*: Adapted from [14].

The major dopamine pathways in the brain are the nigrostriatal pathway (pathway 1 in Fig. 3), which extends between the substantia nigra and the striatum; the mesolimbic pathway (pathway 2 in Fig. 3), which connects the ventral tegmentum in the midbrain and nucleus accumbens; the mesocortical pathway (pathway 3 in Fig. 3), which extends from the ventral tegmentum to the cortex; and the tuberoinfundibular pathway (pathway 4 in Fig. 3), which originates in the hypothalamus and projects into the pituitary gland.

As discussed before, the most prominent hypothesis regarding the etiology of schizophrenia is the dopamine theory. The ability of typical antipsychotic drugs to diminish positive psychotic symptoms was shown to be initiated by the blockade of the dopamine $D_2$ receptors in the mesolimbic nuclei (second pathway in the diagram), especially the stria terminalis and the extended amygdale.

### 3.2 Dopamine and Serotonin Receptors in Schizophrenia

Most drugs used in schizophrenia have been shown to have affinities for several dopamine receptor subtypes. By antagonizing dopamine receptors, it is possible to block hallucinations during the active phase of schizophrenia [17]. This deactivates the biochemical processes

**Figure 3** Dopamine pathways.

**Figure 5** Dopamine receptors and negative symptoms.

normally initiated by dopamine binding. The brain responds to this receptor blockade by making extra dopamine receptors (Figs. 4 and 5). These extra receptors restore the cell's sensitivity to dopamine. The brain also compensates by increasing dopamine synthesis. The increase in dopamine synthesis lasts 1–2 weeks from the start of therapy, which is the same time required for the medication to become effective. Most effective antipsychiatrics, typical as well as atypical, have affinity for dopamine receptors. When drugs block dopamine receptors in the basal ganglia, the symptoms of schizophrenia are reduced. Five dopamine receptor subtypes ($D_{1-5}$) have been discovered so far. Their function is to bind to dopamine secreted by presynaptic nerve cells. The $D_1$ and $D_5$ receptors are involved in episodic memory, emotion, and cognition, which are disturbed in schizophrenic patients. There is less $D_1$ binding of dopamine in schizophrenic patients as compared to healthy sub-

jects as a result of fewer $D_1$ receptors. Certain antipsychotic drugs stimulate $D_1$-regulated pathways, which increases the $D_1$ to $D_2$ activity balance in the brain. This balance can also be regained by the release of dopamine. The $D_2$ is the second most abundant dopamine receptor in the brain. $D_2$ receptor blockade is the main target for antipsychotic drugs because there is a higher density of $D_2$ in schizophrenic brains. According to studies, there is a loss of $D_3$ expression in the parietal and motor cortices of postmortem, schizophrenic brains. This may be due to either the course of the disease or the therapy given to the patient during the course of the disease. Not much is known about $D_5$ due to the lack of drugs that are selective for it [18, 19].

Haloperidol was synthesized in 1956. Haloperidol is the most widely used typical antipsychotic that binds nonselectively to a broad range of receptors [18]. It can bind to dopamine $D_1$ and $D_2$, 5-$HT_2$, histamine $H_1$ and $\alpha_2$-adrenergic receptors in the brain; however, its major site of action is the $D_2$ receptor. Long-term use of this drug results in an irreversible motor disorder involving the orofacial muscles and extremities. Haloperidol produces more EPS but less histaminic, orthostatic, and anticholinergic side effects. On the other hand, chlorpromazine produces less EPS but more histaminic (sedation), $\alpha_1$-adrenergic (orthostatic hypotension), muscarinic (anticholinergic side effects). Typical drugs have stronger affinity for the $D_2$ receptors rather than the 5-$HT_{2A}$ receptors and do not decrease negative symptoms of schizophrenia. First-generation antipsychotic (FGA) drugs reduce the positive symptoms of schizophrenia. The first-generation antipsychotic drugs cause severe extrapyramidal side effects such as acute dystonic reaction, subacute parkinsonism, akathisia, and tardive kinesia or dystonia, due to strong $D_2$ blockade. These EPS side effects have been and still are major concerns in the therapeutic community. [19].

More recently (1990s), it has become widely accepted that antipsychotic drugs, the second-generation antipsychotics (atypicals), that block both serotonin and dopamine, improve therapeutic outcomes compared with those that mainly block $D_2$ receptors. Serotonin is a neurotransmitter and neuromodulator. Therefore, it can control dopamine levels in the brain. Higher affinity for the 5-$HT_{2A}$ receptor compared to the $D_2$ receptor was the basis for the difference between typical and atypical agents. Another major revolution of receptor bindings between typical and atypical antipsychotic drugs is that atypical drugs with low affinity for $D_2$ receptors (e.g., clozapine and quetiapine) have higher dissociation rates from $D_2$ receptors. Their ability to bind shortly and loosely explains their less EPS side effects. The atypical drugs arranged in order of descending dopamine affinity are as following: risperidone > ziprasidone > olanzapine > clozapine > quetiapine. EPS, which requires very high levels of receptor occupancy, occurs occasionally with risperidone, which is a strong of second-generation dopamine antagonist, but occurs rarely with the other second-generation antipsychotic drugs.

Elevated levels of serotonin (5-HT) are found in the schizophrenia patient. Serotonin has been implicated in a variety of behaviors and somatic functions that are disturbed in schizophrenia: cognition, including memory, perception, and attention, sensory gating, mood, aggression, sexual drive, appetite, energy level, pain sensitivity, endocrine function, and sleep. Many of these functions are clearly relevant to the etiology of positive and negative symptoms and the cognitive impairments that constitute the core abnormalities of schizophrenia. Serotonin receptors include 5-$HT_{1A}$, 5-$HT_{2A}$, 5-$HT_{2C}$, 5-$HT_3$, 5-$HT_6$, and 5-$HT_7$, but most of the antipsychotic drugs are developed on the basis of 5-$HT_{2A}$. Some medications such as clozapine and olanzapine have equivalent affinity for 5-$HT_{2A}$ and 5-$HT_{2C}$, whereas others such as risperidone and ziprasidone have more selectivity for 5-$HT_{2A}$. Based on some evidence, 5-$HT_{A1}$ antagonists improve learning and memory by blocking the inhibitory effects of 5-$HT_{A1}$ receptors on the firing of hippocampal neurons. This suggests that a partial agonist acting as an antagonist may be beneficial for schizophrenia. Atypical drugs also have some antagonist effect on $\alpha_1$ and $\alpha_2$ adrenoceptors. Risperidone, clozapine, olanzepine, zotepine, quetiapine, sertindole, and ziprasidone are potent $\alpha_1$ antagonist. The $\alpha_1$ receptor antagonists have shown to increase dopamine efflux in the shell but not the core of the nucleus in the limbic system. Clozapine and other atypical drugs have shown cardiovascular side effects because of their $\alpha$-adrenergic activities.

### 3.3 Pharmacotherapy of Schizophrenia

The term *atypical antipsychotics* refers to drugs that do not cause extrapyramidal symptoms or tardive dyskinesia in humans. Unlike typical antipsychotics, which may increase levels of prolactin, the atypicals have less or no effect on prolactin levels, and they decrease the negative effects of schizophrenia. These drugs are stronger antagonist of 5-$HT_{2A}$ with lower affinity for $D_2$. Since the newer drugs are more selective on limbic system, they improve cognition as well as positive and negative symptoms. As far as psychosis, both typical and atypical drugs work the same. It appears that the atypical drugs as a class produce substantial weight gain compared with conventional drugs. Histaminic activity correlates with weight gain as well as incidence of diabetes. Atypical antipsychotic drugs have also been associated with alterations in glucose metabolism. In addition, they

cause increased rates of cardiovascular disease, such as hypertension and coronary artery disease [19].

In order to understand how the mechanism of action of typical and atypical antipsychotic drugs differ, a study analyzed the affinities, the occupancies, and the dissociation time-course of various antipsychotics at dopamine $D_2$ receptors and at serotonin (5-HT) receptors, both in the test tube and in live patients [20]. According to this study, the older antipsychotics such as trifluperazine, chlorpromazine, fluphenazine, haloperidol, and flupenthixol bind more tightly than dopamine itself to the dopamine $D_2$ receptor. On the other hand, the newer antipsychotics such as quetiapine, remoxipride, clozapine, olanzapine, sertindole, ziprasidone, and amisulpride all bind more loosely than dopamine to the dopamine $D_2$ receptor. These tight and loose binding data agree with the rates of antipsychotic dissociation from the human-cloned $D_2$ receptor. In this study they measured the time of the dissociation of medication from the receptors. The results for older drugs showed very slow dissociation of about 30 min, while radioactive quetiapine, clozapine, remoxipride, and amisulpride dissociate rapidly, in less than 60 s. This study suggests that atypical drugs work by occupying $D_2$ receptors and then rapidly dissociating to allow normal dopamine neurotransmission. This keeps prolactin levels normal, spares cognition, and lowers EPS side effect. This study also confirms that the newer drugs block 5-$HT_{2A}$ receptors at the same time as they block dopamine receptors. According to the study, the antipsychotic threshold occupancy of $D_2$ for antipsychotic action remains at about 65% for both typical and atypical antipsychotic drugs, regardless of whether 5-$HT_{2A}$ receptors are blocked or not. At the same time, the antipsychotic threshold occupancy of $D_2$ for eliciting EPS remains at about 80% for both typical and atypical antipsychotic drugs, regardless of the occupancy of 5-$HT_{2A}$ receptors.

Abilify (aripiprazole) is an antipsychotic drug with a new mechanism of action. It works as a partial agonist against dopamine $D_2$ receptors and differs from other antipsychotics in this respect. Pharmacological studies demonstrate that Abilify can be a high-affinity partial agonist, a full agonist, or an antagonist at the dopamine receptor. It shows inhibitory action when large amounts of dopamine are released in the brain and stimulatory action when only small amounts of dopamine are released. Abilify is known as a dopamine system stabilizer (DSS). It also improves both positive and negative symptoms of schizophrenia considered to be caused by dopamine abnormalities [21]. It is expected that this drug can be used for long periods since it is less likely to cause sleepiness or weight gain. There are several other important components, such as glutamatergic neurotransmission, and an array of receptor subtypes for both dopamine and serotonin. Although antipsychotics can also have antimuscarinic and antihistaminic properties and cause $\alpha_1$-adrenergic and $\alpha_2$-adrenergic blockade, these properties are thought to be related to different side effect profiles rather than to antipsychotic efficacy. The pharmacological profile of Abilify differs from typical and atypical drugs in being a partial agonist as opposed to an antagonist at the dopamine receptor. Abilify has a low serotonin/dopamine affinity ratio and a high affinity for dopamine receptor. Second-generation antipsychotic drugs have been distinguished from typical agents by a high serotonin/dopamine affinity ratio and a low affinity for dopamine receptor.

In conclusion, typical antipsychotic drugs such as haloperidol had shown their effectiveness mainly by blocking dopamine ($D_2$) receptors in the mesolimbic system. Atypical drugs have promising results due to both their serotonin and dopamine antagonist activities. Clozapine was the first atypical antipsychotic drug that introduced the important role of serotonin receptors in the effectiveness of antipsychotic medication. Typical antipsychotic drugs have a stronger blocking property for the serotonin receptor relative to dopamine blocking property. Controlling dopamine and dopamine receptors is essential for the treatment of schizophrenia. Partial dopamine receptor agonists, which may act as an agonist at presynaptic dopamine receptors and antagonist at postsynaptic dopamine receptors, are a new class of drugs that have promise in the future. Partial dopamine agonists may modulate dopamine neurotransmission more adequately than pure antagonists by producing a mix of direct agonist and antagonistic effects. Multireceptor agents appear to be more promising as antipsychotic agents for the majority of psychiatric patients. Atypical compounds are in early stages of development. Among them is iloperidone (Zomaril), by Novartis. Zomaril is one of a new class of drugs known as serotonin/dopamine receptor antagonists, which inhibit serotonin and dopamine activity by binding to these receptors in the brain. Specifically, it is a mixed 5-$HT_{2a}$ /dopamine $D_2$ antagonist. This drug is in phase III clinical trial. Solvay Pharmaceuticals is in phase III testing of Bifeprunox (DU127090), a mixed dopamine $D_2$ partial agonist and 5-$HT_{1a}$ partial agonist. This atypical antipsychotic targets both the positive and negative symptoms of schizophrenia. ACP-103, a potent and selective 5-$HT_{2A}$ inverse agonist, is in phase II testing by ACADIA Pharmaceuticals as adjunctive therapy. The hope is that adding ACP-103 to currently available antipsychotic agents may achieve the best combination of dopamine receptor blockade and 5-$HT_{2A}$ inverse agonism. In theory, this should reduce adverse effects while expanding the range of efficacy [17, 19].

Research into glutamate drugs for schizophrenia has focused on compounds that can enhance *N*-methyl-D-aspartate (NMDA) receptor function as well as those that can reduce glutamate release. Based on a study, inhibition of glycine reuptake by sarcosine, an antagonist of the glycine transporter 1, was more effective at reducing both positive and negative symptoms than was direct activation of the glycine/D-serine site by D-serine [22]. Together with direct activators of the NMDA receptor, future treatments are likely to include drugs that enhance the production of endogenous modulators of the NMDA receptor, such as serine racemase, an astrocytic enzyme synthesizing D-serine. Interestingly, expression of this enzyme was recently reported to be altered in schizophrenia. The potential to target activity and expression of a multitude of synaptic and extrasynaptic molecules involved in synthesis and control of NMDA receptor function could produce new drugs with enhanced efficacy in patients with schizophrenia [23]. A member of a new class of antipsychotic drugs, LY2140023 is still in early stage clinical development. Lilly's LY2140023 differs from established antipsychotic drugs by targeting glutamate rather than dopamine or serotonin receptors. The result of studies suggested that LY2140023 can be a safe and well-tolerated drug with fewer side effects of hyperprolactinaemia, extrapyramidal symptoms, and weight gain (see the Eli Lily website) [24].

In order to improve treatment outcome, it is important for clinicians to be familiar with different receptor activity of old and new generation of antipsychotic drugs. By knowing the receptor activity, it is easy to predict the side effect profile of medication, which would increase the chances of achieving the best possible treatment outcome.

## 4 ADVERSE EFFECTS OF ANTIPSYCHOTICS

Antipsychotic medications are associated with a variety of adverse effects in addition to their therapeutic effects in controlling symptoms of mental illness. Recently, much of the discussion has been focused on the association of psychotropic medications, specifically second-generation antipsychotics (SGAs) and metabolic effects such as glucose dysregulation (Table 4) and lipid disorders. Due to the impact of diabetes mellitus and hyperlipidemia on coronary heart disease, clinicians need to be aggressive in monitoring the emergence of these adverse events. Here we discuss the effects of psychotropic medications on metabolic function, sexual function, prolactin levels, and cardiovascular health.

**TABLE 4 Prevalence of Type 2 Diabetes Mellitus in Patients Receiving Antipsychotic Agents**

| Drug | Patients with Type 2 DM (%) |
|---|---|
| Fluphenazine | 4.5 |
| Risperidone | 6 |
| Haloperidol | 6.6 |
| Olanzapine | 11 |
| Clozapine | 15.5 |

### 4.1 Metabolism and Weight Gain

Patients with mental illness have a higher prevalence of weight gain and obesity compared to patients without mental illness. Major complications associated with obesity are cancer, congestive heart failure, coronary heart disease, diabetes mellitus (DM), dyslipidemia, gallstones, genitourinary problems, hypertension, menstrual problems, sleep apnea, and stroke. Obesity-related illnesses cost the nation $117 billion in 2000 alone and are responsible for as many as 300,000 premature deaths each year. Obesity can be 1.5–2 times more prevalent in people with schizophrenia and affective disorders than in the general population. Recent findings suggest that psychotropic medications used to treat this population also contribute to weight gain.

There are several hypotheses on the metabolic effect of antipsychotics. They are believed to act on the hypothalamic feeding center and directly stimulate appetite. Recent evidence suggests that antagonism of serotonin 2C (5-$HT_{2C}$), dopamine (DA), adrenergic ($\alpha$), histamine type 1 ($H_1$), and glutamine receptors may play a role in antipsychotic-related weight gain. Other neurotransmitters such as acetylcholine as well as metabolic and biologic mechanisms may also be involved. Apart from these, environmental, psychological, and lifestyle factors are definitely key contributors to the development of weight gain in patients treated with antipsychotics.

Agents that stimulate 5-$HT_{2C}$ receptors—such as fenfluramine and *m*-chlorophenyl-piperazine (mCPP) (a metabolite of trazodone and nefazodone)—have been associated with weight loss. Conversely, agents that antagonize 5-$HT_{2C}$ and $H_1$ receptors have been hypothesized to increase appetite and cause weight gain. Studies demonstrate an exponential relationship between antipsychotic $H_1$ receptor affinities and maximum weight gain. Clozapine and olanzapine have very strong binding affinities to 5-$HT_{2A}$, 5-$HT_{2C}$, and $H_1$ and muscarinic ($M_1$) receptors and less affinity for the $D_2$ receptors. These neurotransmitter systems and receptor subtypes appear to help regulate food intake and energy homeostasis and may play a role in weight gain associated with antipsychotic use. The preferential antagonism of 5-$HT_{2A}$ versus $D_2$ receptors may also

explain the advantage of SGAs versus FGAs in alleviating negative symptoms of schizophrenia and better side effect profile. There is also recent evidence that polymorphism of the 5-$HT_{2C}$ receptor gene may be involved in protection against antipsychotic-induced weight gain [25].

Three peptides are implicated in the regulation of food intake, energy expenditure, and body energy balance: galanin, neuropeptide Y, and leptin. Among the three, leptin has been more extensively investigated. Leptin, a member of the interleukin-6 cytokine family, is found in multiple tissues and secreted by adipose cells. Leptin plays an important role in the regulation of insulin secretion and energy metabolism in fat cells and skeletal muscle. Since leptin levels are chronically increased in obese individuals, obesity may be associated with malfunctioning of leptin receptors, a condition called leptin resistance. In patients with new-onset DM induced by antipsychotic agents, leptin levels are elevated. There is evidence with clozapine that the increase in leptin may be directly due to the drug, not just due to weight gain. A small study challenged this correlation and found no difference in leptin levels between patients with chronic schizophrenia and matched controls [26]. Improving responsivity to leptin in obese patients may lead to weight loss, although the efficacy of exogenous leptin administration in decreasing weight is yet unknown. In addition, there are numerous other neurotransmitters and peptides that have been implicated in the regulation of appetite, eating behavior, and control.

Although weight gain is associated with both FGAs and SGAs, studies have shown that there are differences in weight gain potential among antipsychotic agents [27]. Long-term treatment with SGAs has demonstrated that aripiprazole and ziprasidone are associated with less weight gain, while olanzapine and clozapine are associated with more weight gain. Patients with lowest baseline body mass index (BMI) have the greatest weight gain, independent of dose. Clozapine is associated with greater mean weight gain than olanzapine, risperidone, or ziprasidone. Risperidone—with a lower weight gain potential than most atypicals—displays high affinity for 5-$HT_{2A}$ and $\beta_1$ receptors and a lower affinity for 5-$HT_{2C}$ receptors than for $D_2$ receptors. The weight gain potential of ziprasidone is even less than that of risperidone and the exact mechanism is unknown.

### 4.2 Lipid Abnormalities

The association between SGAs and hypertriglyceridemia has been established in a wide range of studies. In addition to age, sex, and low- (LDL) and high-density lipoproteins (HDL), plasma triglycerides (TG) is an independent risk factor for the development of coronary atherosclerosis and coronary heart disease (CHD). Due to the increased prevalence of heart disease and associated mortality in the schizophrenia population, the potential for SGAs to increase TG is an important concern.

Both hyperlipidemia and hypertriglyceridemia are thought to be associated with insulin resistance. In extreme cases of hypertriglyceridemia (i.e., development of pancreatitis), the expected physiologic response is the decreased production of islet cells and decreased glucose utilization. Although all atypicals (with the exception of ziprasidone and aripiprazole) increase serum TG to some degree, severe hypertriglyceridemia occurs predominantly with clozapine and olanzapine. Although both drugs have favorable efficacy profiles, the mechanism of their antipsychotic activity may include altering the various lipid pools. Ziprasidone and aripiprazole usually do not elevate lipid levels.

In a small clinical study, researchers evaluated the effects of olanzapine on weight, fasting total cholesterol (TC), and TG in 25 patients with schizophrenia and related psychoses. After 12 weeks of olanzapine treatment, the group mean body weight increased 5.4 kg ($P < 0.02$) [28]. Although there was no significant change in cholesterol levels, the mean TG levels rose by 37%. In a 5-year naturalistic study of patients treated with clozapine, researchers found that weight gain increased until 46 weeks after drug initiation [29]. There was no significant increase in total cholesterol and significant increase in serum TG levels. A univariate analysis also correlated elevated serum TG levels with increased risk for coronary artery disease. Clozapine was also associated with the greatest increases in weight, lipid levels, and blood glucose levels. Triglyceride levels have been reported to be increased in numerous studies involving clozapine and olanzapine. In one study of four patients with psychotic disorders, serum TG levels were decreased after switching therapy from clozapine to risperidone [30]. In two of the four patients, clozapine was reinstated after risperidone was discontinued and serum TG levels increased. This finding is consistent with previous reports involving clozapine rechallenge. In a study with olanzapine and risperidone, olanzapine was found to have 4.1 kg weight gain compared to risperidone (2.3 kg) over 7 months [31]. Long-term data (greater than 8 weeks) for quetiapine and weight gain is not available.

### 4.3 Diabetes Mellitus

Diabetes mellitus is a serious, life-threatening illness that can lead to heart failure, stroke, renal failure, and blindness. Recent data collected by the Schizophrenia Patient Outcomes Research Team (SPORT) suggest that people with schizophrenia may be at increased risk

for type II DM due to side effects of antipsychotic medications (especially SGAs), poor overall physical health, sedentary lifestyles, poor diet, and inadequate health care [32]. Schizophrenia and bipolar disorders have been associated with an elevated risk of DM (primarily type II) and disturbances in glucose regulation. A recent Veterans Affairs study found that the rate of diabetes (diagnosed) in men with schizophrenia was six to eight times higher than men without schizophrenia as estimated by the National Health and Nutrition Examination Survey (NHANES) study in 1998 [33, 34]. Type II DM as well as impaired glucose tolerance tests have been associated with some conventional as well as some atypical antipsychotic agents. Individuals with schizophrenia are also at higher risk for developing diabetic ketoacidosis due to the lack of consistent medical care or due to drugs that have a propensity to increase weight.

Several mechanisms may explain the association between SGAs and DM. Both olanzapine and clozapine show great affinities for 5-$HT_{1C}$ and 5-$HT_{2C}$ receptors. One study postulated that clozapine and olanzapine may damage pancreatic islet cells and cause dysregulation of the sympathetic nervous system. In addition, decreased serum insulin by way of depressed pancreatic β-cell responsiveness to serum glucose may be related to 5-$HT_{1A}$ antagonism seen with these newer antipsychotic agents. In a recent study, 15% of patients with a first episode of schizophrenia (medication naïve) had impaired fasting glucose and insulin resistance compared to matched controls [35].

The major problem for patients taking antipsychotic medications is that antipsychotic medications can increase weight and increase levels of adiposity. In patients with schizophrenia, intra-abdominal fat (observed by computed tomography) was significantly elevated versus matched controls [36]. The acute stress of psychosis may also affect glucose and insulin levels. In the same study, cortisol levels were significantly elevated in patients with schizophrenia compared to controls. Increasing adiposity increases the risk of type II DM and hyperglycemia, and this occurs via increases in insulin resistance. The main abnormality of DM is hyperglycemia, but this can occur due to defects in insulin secretion, insulin action, or both.

When antipsychotic medications were first introduced with chlorpromazine in the 1950s, several reports were published regarding phenothiazines and their potential to aggravate existing DM and/or induce new-onset type II DM. For example, the introduction of chlorpromazine increased the prevalence of DM in one clinical setting from approximately 4% to approximately 17% [37]. Various groups reported these abnormalities in glucose control, including the National Diabetes Data Group, which added phenothiazines to the list of medications that could disturb glucose metabolism in the 1970s. Among atypical antipsychotics, there are also differences in the risk of causing glucose dysregulation. Dibenzodiazepines (clozapine, olanzapine, quetiapine) are associated with DM occurring early in the course of therapy, even without significant weight gain (0–10 lb) (Table 4).

With the emergence of SGAs, there have been increased reports of new-onset DM, exacerbations of existing DM, impaired glucose tolerance, and complications such as diabetic ketoacidosis (DKA) associated with these medications. Although there are reports of new-onset or exacerbation of DM related to many of the atypical agents, clozapine and olanzapine are the ones most frequently cited (Table 4). Clozapine and olanzapine cause an increase in body weight more than other agents, and this in itself increases the risk for diabetes. However, there appear to be other mechanisms involved that are independent of weight. In a study of patients with schizophrenia treated with clozapine, olanzapine, risperidone, or FGAs, patients on olanzapine had significantly elevated glucose levels at all time points compared with those on typical agents and untreated controls [38]. There was no significant increase in risperidone-treated patients compared with patients on FGAs; however, fasting and postloading glucose levels were greater in patients on risperidone when compared with normal controls. There were treatment-related increases in insulin levels, suggesting that the primary defect may be due to tissue sensitivity rather than a secretory defect.

In an epidemiologic study of 19,637 patients with schizophrenia in the United Kingdom, the odds ratio (OR) for the development of DM while taking olanzapine was nearly 6 times the rate in those not receiving any antipsychotics [39]. The OR for those on risperidone and FGAs were approximately 2 and 1.4, respectively. In a retrospective review of patients treated with an SGA who have also been treated for DM, 11 out of 14 patients had acute elevations in glucose levels (fasting blood glucose > 145 mg/dL) after being treated with clozapine, olanzapine, or quetiapine [40]. Five patients developed DKA and were referred to a tertiary care institution for treatment. The median time to onset of DKA was 33 days.

Researchers have noted that treatment with clozapine results in a cumulative risk of diabetes. In a 5-year study of clozapine-treated patients, new cases of DM continued to rise throughout the observation period [29]. By the end of the study, 36.6% of the sample had been diagnosed with DM. There were also significant increases in weight and lipid levels in patients receiving clozapine. Federal regulations now require manufacturers of six SGAs to include labeling language

warning about an increased risk of patients developing diabetes.

### 4.3 Monitoring of Weight Gain, Lipids, and Diabetes and Therapeutic Considerations

Since most of the weight gain with antipsychotic agents occur within the first year, monitoring of patients during this period is crucial. Clinicians need to monitor weight by including a BMI at baseline and periodically thereafter. In addition to baseline BMI, fasting glucose, waist circumference, lipids, and blood pressure need to be monitored. Patients also need to be educated in terms of lifestyle patterns and monitoring of their own weight. Signs and symptoms of DM and DKA are also important patient education points. Clinicians also need to assess risk factors for DM and coronary artery disease as outlined by national guidelines (Table 5).

The level of monitoring for glucose abnormalities also needs to be heightened among clinicians. This will be especially important in patients with risk factors such as increased BMI, family and personal history of glucose intolerance, smoking, and other cardiovascular (CV) risk factors. Beyond mere monitoring of weight, clinicians who understand the neuropharmacology of obesity may be able to recommend alternative drugs or facilitate drug switches to alleviate or reverse psychotropic drug-induced weight gain. To manage psychotropic drug-induced weight gain, one can either treat the weight gain or switch medications. Switching to an agent that does not lead to weight gain is conceivable but not always realistic. All available substitutes may share the same undesirable qualities. Some patients can, however, have very different responses to drugs that share the same mechanism, so switching to a drug within the same class may be an option. This may be particularly true for the typical antipsychotics loxapine and molindone, which seem to generate the least amount of weight gain among the antipsychotics. A weight loss program that produces a loss of 0.5–1% body weight per week is considered safe and acceptable. Moderate obesity can be managed by reducing food intake by 500 calories with dietary consultation and exercising 30 min each day. For patients with metabolic syndrome, correcting the underlying causes of the features, such as obesity, physical inactivity, and lipid dysfunction is recommended.

**TABLE 5 Monitoring and Assessment Parameters, Education, and Management**

*Monitoring and Assessment Parameters*

- Weight and Height (BMI) → BL, 4, 8, 12 weeks, quarterly
- Waist circumference → BL, annually
- Fasting glucose → BL, 12 weeks, annually
- Fasting lipid panel → BL, 12 weeks, every 5 years
- Blood pressure → BL, 12 weeks, annually
- Assess DM risk factors
- Assess CV risk factors

*Education*

- Nutrition and weight management
- Physical activity
- Signs/symptoms of DM
- Signs/symptoms of DKA

*Management*

- If on an FGA, consider a SGA
- Avoid clozapine and olanzapine in patients with risk factors for CHD, DM, or in obese patients or in patients receiving drugs that may increase weight
- If ≥ 5% weight gain, consider switching (by cross-titration) to another antipsychotic; continue with weight loss education and nonpharmacologic management
- If develop severe hyperglycemia and/or signs/symptoms of DKA, refer immediately for medical management
- If BMI ≥ 30 kg/m$^2$ or BMI ≥ 27 kg/ m$^2$ + cardiovascular risk factors, consider pharmacotherapy for weight loss (e.g., amantadine, nizatidine, orlistat, sibutramine, topiramate)

***Hyperprolactinemia*** Hyperprolactinemia is a concern with antipsychotic medications, and compliance may often be adversely affected with this negative association. The link between antipsychotics and hyperprolactinemia has significant implications for the short- and long-term outcomes in the treatment of schizophrenia. Compared to conventional antipsychotics, SGAs are much less likely to increase prolactin levels (Table 6).

**TABLE 6 Effects of Antipsychotics on Prolactin Elevation**

| | $D_2$ Binding Affinities | Prolactin Elevation |
|---|---|---|
| *First-Generation Antipsychotics* | | |
| Chlorpromazine | High | Moderate |
| Fluphenazine | High | Moderate |
| Haloperidol | High | Moderate |
| Perphenazine | High | Moderate |
| Thioridazine | High | Moderate |
| *Second-Generation Antipsychotics* | | |
| Clozapine | Moderate | 0 |
| Olanzapine | Moderate | 0 |
| Quetiapine | Minimal | 0 |
| Risperidone | High | 0 to moderate (dose-related) |

[a]$D_2$—dopamine receptor type 2.

Prolactin is a polypeptide hormone secreted by the lactotroph cells of the anterior pituitary gland. The primary physiologic role of prolactin is the induction of lactation. However, prolactin interacts with other central nervous system (CNS) and peripheral processes. The tuberoinfundibular pathway is involved in the regulation of prolactin secretion through DA neurons. Blockade of DA receptors in the tuberoinfundibular pathway would reverse prolactin inhibitory effects and lead to hyperprolactinemia.

The central blockade of the $D_2$ receptor by antipsychotics is responsible for the pathogenesis of antipsychotic-induced prolactin release. The main physiological effects of prolactin are the suppression of gonadal activity and induction of the synthesis and secretion of milk. Hyperprolactinemia is seldom detected but can have serious consequences. The clinical effects usually occur when levels are between 30 and 60 mcg/L or higher. Some of the manifestations of hyperprolactinemia include decreased bone mineral density and osteoporosis, galactorrhea, breast enlargement, anovulation, infertility, amenorrhea, increased risk of cardiovascular disorders, increased risk of tardive dyskinesia, increased risk of breast cancer, mood disorders (anxiety, depression, hostility), decreased testosterone levels and sperm mobility, sexual dysfunction, decreased libido and arousal, and an- or hypo-orgasmia.

Premenopausal women may present with menstrual disturbances, galactorrhea, breast engorgement, sexual dysfunction, and infertility. Men may experience gynecomastia, priapism, loss of libido, erectile/ejaculatory dysfunction, and azoospermia. Galactorrhea often goes unnoticed and is therefore underreported. Not all women with hyperprolactinemia suffer from galactorrhea, and, conversely, the symptoms may be present in women with normal levels of prolactin. Galactorrhea may also occur in men although to a lesser degree. Decreased bone density is a long-term consequence of hyperprolactinemia mediated by relative or absolute deficiency of estrogen and testosterone. Prolactin levels inversely affect estrogen and testosterone levels in both men and women. If prolactin is increased, testosterone and estrogen are decreased. This in turn is associated with decreased bone density, which may predispose patients to osteoporosis. Estrogen may have protective effects against arteriosclerosis, hypertension, and cholesterol. The low estrogen levels that commonly occur with hyperprolactinemia may increase the rate of cardiovascular disorders in this group.

The normal range of prolactin levels in nonlactating subjects is between 1 and 25 mcg/L. One study established that prolactin levels in patients with schizophrenia are normal prior to receiving treatment for psychosis, alluding to the fact that the schizophrenia itself does not appear to affect prolactin [41]. Risperidone and FGAs raise prolactin levels, but clozapine, quetiapine, and olanzapine do not due to their lack of dopamine blockade within the tuberoinfundibular tract. Second-generation antipsychotics as a group cause less hyperprolactinemia than conventional antipsychotics with the exception of risperidone. The decreased risk for hyperprolactinemia may be due to weaker dopamine $D_2$ antagonist effects or higher ratios of 5-$HT_2$ to $D_2$ antagonist effects of SGAs. Risperidone at higher doses has been shown to produce increases in prolactin similar to conventional antipsychotics, although at lower doses, risperidone may have higher elevations compared to haloperidol. At the opposite end of the spectrum, clozapine and quetiapine produce minimal sustained increases in prolactin that are similar to placebo. Correlations between prolactin elevations and clinical symptoms have not been established. High-potency antipsychotics have the most impact on serum prolactin level since they are the most potent $D_2$ receptor blockers. Studies comparing the effects of haloperidol and quetiapine concluded that quetiapine was not associated with increases in prolactin secretion [42]. Clozapine, the prototypical atypical antipsychotic, is not associated with hyperprolactinemia. One trial found that male patients with elevated prolactin levels and treatment-refractory schizophrenia had a decrease in prolactin levels after being switched to clozapine [43]. In one study, 20 female patients with schizophrenia on risperidone were switched to olanzapine [44]. After the switch, prolactin levels were significantly reduced, demonstrating the reversal of hyperprolactinemia in patients previously treated with risperidone. Sustained elevations in prolactin levels were not observed with quetiapine or ziprasidone. In addition, aripiprazole has not been associated with an increase in prolactin levels.

*Monitoring* Hyperprolactinemia can be defined as plasma prolactin levels of >20 mcg/L for men and >25 mcg/L for women. Prolactin levels should be measured at baseline when initiating agents that have the potential to increase prolactin. If clinical symptoms emerge, prolactin levels may be useful as a monitoring parameter. Only the presence of clinical symptoms, not an elevated prolactin level alone, should direct changing a patient's drug treatment strategy.

### *Cardiovascular Disturbances*

*Epidemiology* The prevalence of cardiovascular disease is high in schizophrenic patients. This increased risk has been attributed to multiple causes ranging from platelet aggregation to poor living conditions and life-

style differences such as diet. Antipsychotic medications are associated with cardiovascular side effects that can have serious consequences to the patient. Risk factors for cardiovascular adverse effects with the atypical antipsychotics include known cardiovascular disease, electrolyte disturbances (particularly hypokalemia and hypomagnesemia), genetic characteristics, increasing age, female sex (for QTc lengthening and torsade de pointes), autonomic dysfunction, high doses, the use of interacting drugs, and psychiatric illness itself.

*Clinical Evidence*

BLOOD PRESSURE Hypotension is a significant side effect encountered with SGAs. Adrenergic blockade may result in a number of risk factors, such as syncope, fractures, increased anginal episodes, and orthostatic hypotension. The agents that most commonly cause hypotension include clozapine, quetiapine, risperidone, and olanzapine. Olanzapine does not block $\alpha$-adrenergic receptors and has not been linked to orthostatic hypotension, although dizziness has been reported in some patients. Risperidone can occasionally cause orthostatic dizziness, hypotension including orthostatic hypotension, tachycardia including reflex tachycardia, and hypertension. The least hypotensive effects are reported with ziprasidone and haloperidol. Antipsychotic drugs in combination with cardiovascular medications such as methyldopa, diuretics, adrenergic blockers, calcium antagonists, angiotensin-converting enzyme inhibitors, angiotensin-II receptor blockers, nitrates, and others may aggravate the hypotensive effects.

CONGESTIVE HEART FAILURE AND MYOCARDITIS Some of the SGAs report congestive heart failure as a direct cardiac effect. This effect has been reported infrequently (1/100–1/1000) with olanzapine and rarely (<1/1000) with clozapine and quetiapine. The vasodilator effects of the atypicals may counteract any major hemodynamic deterioration. Reports of myocarditis and cardiomyopathy associated with clozapine have raised concerns that this agent may be associated with other forms of cardiac toxicity. In January 2002, Novartis Pharmaceuticals Corp. reported 213 cases of myocarditis, 85% of which occurred while patients were taking recommended doses of clozapine within the first 2 months of therapy. Monitoring for cardiac toxicity is particularly challenging because its manifestations (e.g., tachycardia, fatigue, orthostatic hypotension) are frequently observed in clozapine-treated patients. This is especially true during dosage titrations. Clozapine received a black-box warning in February 2002 for the increased risk of fatal myocarditis, especially but not limited to the first month of treatment. Clozapine should be discontinued if a patient presents with new-onset fatigue, dyspnea, tachypnea, fever, chest pain, palpitations, and symptoms of heart failure or electrocardiograph findings of ST-T wave abnormalities or arrhythmias. Clozapine is also contraindicated in patients with cardiac failure. In patients suffering from cardiovascular disorders, the initial dose should be 12.5 mg given once on the first day, and dosage increase should be done slowly and in small increments.

QTc INTERVAL PROLONGATION QT interval is an electrocardiograph (ECG) measure that describes both depolarization and repolarization of the ventricles. QT interval is usually corrected for heart rate (QTc) since the interval shortens with increasing heart rates. QTc intervals less than 440 are considered normal, and QTc intervals greater than 500 ms place the individual at a significantly increased risk for serious arrhythmias called torsade de pointes (TdP). The arrhythmia can arise from myocardial ischemia, myocarditis, long QT syndrome, and a variety of other causes. They are often self-terminating but can be rapidly fatal if they persist. It would be safest to find a drug that has no effect on the QTc interval, but that alternative does not always exist. It is important to realize that QTc interval prolongation is a warning, not the risk itself. Not all drugs that prolong the QTc interval produce TdP and sudden death. All SGAs can prolong QT intervals to some degree by reducing the flow of repolarizing $K^+$ currents, ultimately making the myocardium more excitable.

QTc prolongation has been reported for all atypical antipsychotics with varying incidences and degrees of severity. Atypical antipsychotics should be used with caution in patients who are being treated with drugs that prolong the QTc interval (e.g., erythromycin, clarithromycin, antiarrhythmic drugs, etc.) During clinical trials, ziprasidone was noted to increase the QTc more than other atypical agents. The best available data come from a Pfizer study upon the FDA's request comparing the effect of ziprasidone, risperidone, olanzapine, quetiapine, thioridazine, and haloperidol on QT interval [45]. After the initial washout period and baseline ECGs, patients were then randomly assigned to receive one of six antipsychotics. For each drug, except thioridazine, the highest dose recommended in the package insert was administered. Blood levels were obtained and repeat ECGs were recorded at the time of maximum drug blood level. In the final phase of the trial, a metabolic pathway inhibitor of that drug was coadministered and repeat ECGs were obtained. Although the dose of thioridazine was only half of the recommended dose, the drug produced the most prolongation. It is interesting to note that risperidone prolonged the QTc interval by almost 12 ms, even though there is no convincing

evidence in the literature that it has ever caused torsade de pointes or sudden death. The FDA has used QTc intervals greater than 500 ms as a clinically significant cutoff.

It is important to complete a cardiovascular assessment before prescribing an antipsychotic and to consider ordering an ECG for patients with personal or a family history of syncope, personal history of angina pectoris, myocardial infarction, congestive heart failure, cardiac arrhythmia, hypomagnesemia, or significant risk factors. An ECG also is required or strongly recommended before prescribing the antipsychotic drugs most commonly associated with QT prolongation and torsade de pointes [e.g., droperidol, haloperidol in large doses intravenously (IV) such as 100 mg/day, mesoridazine, pimozide, and thioridazine).

The FDA has strengthened the warning labels required for these agents, adding black-box warnings about the risks of prolonged QTc intervals, torsade de pointes, and sudden death for droperidol, mesoridazine, and thioridazine. Thioridazine, for example, is indicated only for patients with schizophrenia who fail to show an acceptable response to other antipsychotic drugs. Its use is contraindicated in patients who take fluvoxamine, propranolol, and pindolol, any drug that inhibits the cytochrome P450 2D6 isoenzyme (e.g., fluoxetine, paroxetine), and agents known to prolong the QTc interval. Use of thioridazine also is contraindicated in patients known to have reduced levels of the cytochrome P450 2D6 isozyme, as well as in patients with congenital LQTS or a history of cardiac arrhythmias.

Of the SGAs, ziprasidone is frequently cited to have increased risk for prolonged QTc interval, although there is no black-box warning for this drug. Although the FDA does not require a baseline ECG monitoring for patients initiated on ziprasidone, clinicians are urged to look for warning signs of prolonged QTc. In addition, electrolyte disturbances (e.g., $K^+$ depletion) that may increase the risk of TdP should be aggressively treated to prevent morbidity and mortality. Psychiatrists are advised to read the warnings and prescribing information in the labeling of all antipsychotics for potential cardiovascular side effects.

CEREBROVASCULAR EVENTS Although SGAs are not approved for the treatment of dementia, these agents at low doses are often used to control the behavioral disturbances associated with dementia. Recently, manufacturers of risperidone and olanzapine have announced that these drugs may be associated with increased rates of cerebrovascular events including stroke and transient ischemic attacks.

The data for risperidone comes from four placebo-controlled trials in 1230 patients [46]. Cerebrovascular adverse events were twice as frequent in the risperidone group (4%) compared to the placebo group (2%). A Dear Healthcare Provider letter was sent in April 2003 by Janssen Pharmaceuticals regarding this finding. Eli Lilly and Company also sent a letter to U.S. health care providers in January 2004 due to study findings that the drug was associated with a 3.5% occurrence of death in elderly patients with dementia compared to 1.5% death in the placebo group [47]. Currently, the package labeling of risperidone and olanzapine include the risk of cerebrovascular events, including stroke in elderly patients with dementia. Risperidone and olanzapine have not been shown to be safe or effective in patients with dementia-related psychosis or behavioral disorders. Physicians should be aware of this potential adverse event and advise patients regarding this potential risk.

Mental illnesses are devastating chronic conditions and usually require long-term treatment to not only treat the initial presentation but to prevent recurrent episodes. Although psychotropic medications have many adverse effects, recent evidence suggests that they also have serious long-term complications that can increase rates of morbidity and mortality in patients with psychiatric disorders. Metabolic disturbances, especially weight gain and glucose abnormalities among atypical antipsychotics, are particularly concerning since patients with schizophrenia and affective disorders are at increased risk for developing obesity and diabetes mellitus. Cardiac disturbances, with the introduction of ziprasidone, cannot be ignored, although typical antipsychotics have been known to carry this risk. Sexual dysfunction and hyperprolactinemia are by no means less concerning than other adverse effects, and they can often lead to treatment nonadherence, relapse, and possibly increased morbidity and/or mortality. Clinicians should be aware of potential adverse effects of psychotropic medications and patient risk factors that may increase their likelihood of developing or exacerbating that condition. Primary prevention is usually the best management option for these serious adverse effects.

## 5 CURRENT DEVELOPMENTS AND FUTURE PROSPECTS

### 5.1 Focus on Neurodegeneration in Schizophrenia

Schizophrenia is associated with abnormal brain development. It is a potentially disabling disorder because of its capacity to destroy our normal capacities for perception, reasoning, and interpersonal relationships. Brain morphological alterations in schizophrenic patients have led to the neurodevelopmental hypothesis; there

is a growing consensus that the disorder may also involve neurodegeneration [48]. Many studies have shown progressive morphological changes in schizophrenic patients. Also, neuroanatomical abnormalities have been observed in patients with schizophrenia. Neurodegenerative process in schizophrenia has been found in some studies. The etiology of neurodegeneration in schizophrenia has not been clearly understood. It must be determined if neurodegeneration is associated to schizophrenia itself or it is caused by antipsychotic medications or genetic factors. Also, there is an intense discussion about possible mechanisms of neurodegeneration in schizophrenia.

Antipsychotic drugs are widely used in schizophrenic patients with the purpose to suppress the negative and positive symptoms. However, there are many adverse effects that have been observed in patients using antipsychotic medications. Many studies have found that longer periods of using antipsychotic medication could be associated with poorer outcomes. Metabolic effects of atypical antipsychotics have resulted in calls to consider the public health implications of new-onset diabetes mellitus, weight gain, and hyperlipidemia. Antipsychotic drugs have been associated with structural brain changes in the development of tardive dyskinesia and with cognitive dysfunction. Moreover, antipsychotic drugs could cause neurotoxicity, decreased neuroplasticity, apoptosis as well as the more specific cellular changes in the brain that could lead to neurodegeneration in schizophrenic patients [49].

Antipsychotic medications can affect the structure and function of neurons via a number of processes. These include neuroplasticity in which gradual cellular changes develop in response to the environment. Several investigators have reviewed how the brains of schizophrenic patients react to the presence of an antipsychotic. They found the loss of striatal neurons and increasing in neuronal size and gliosis, and neurodegeneration in the substantia nigra, 10–20% decreasing in neuronal density in striatum, loss of dendritic spines, and increasing numbers of axon terminals [49]. Neurotoxicity is cellular damage, with hydrolysis of cell membranes and an inflammatory response. For example, haloperidol has led to decreased cell viability, membrane blebs, and retraction of cell extensions in primary hippocampal neurons. Also, it has led to acute reversible injury to dendritic microtubes in the anterior parietal region, the central gray matter, and the hippocampus [49].

Gene expression is also known to be involved in neurodegeneration in schizophrenia [48, 50]. Some genes and chromosomal regions have already been associated with a greater risk for the illness, although no single gene or genes have been definitively identified as causal for schizophrenia. The gene for brain-derived neurotrophic factor (BDNF) has been implicated in the risk for schizophrenia. Each human gene has one or more different structural variants (alleles) that are determined in part by past mutations and their permanent incorporation into the human genome. This is also true for the BDNF gene. Schizophrenic patients with one or two *met* BDNF alleles (instead of the more common *val* allele) had measurably lower abilities to perform tasks of learning and memory, and had abnormal rCBF in medial temporal regions (including the hippocampus) during the performance of tasks of learning and memory. Also, they have lower levels of *N*-acetylaspartate. The *met* BDNF allele's extra load of diminished performance on functions of learning and memory may contribute to the cognitive impairments seen in subjects with schizophrenia [50]. Other recent studies have found that allelic variation in the *Notch4* gene decreases in subjects with schizophrenia [51].

Morphological alterations in the brains of schizophrenia patients have been found mainly in the cerebellum, frontal and temporal lobes, nucleus accumbens, mediodorsal thalamus, and other brain regions [52]. There have been several reports of reductions in the gray matter volume of cortical structures [51, 53]. Reports of decreases in the volume of the entire temporal lobe [52] have been followed by reports of hippocampal volume reductions [51, 54–56] in patients with schizophrenia. Similarly, reductions in the volume of the parahippocampal gyrus were reported [51]. A general decrease of brain mass from the onset of the disorder has also been reported [52]. These pathological findings may be observed since the earlier psychotic episodes, and they are more evident in patients who have suffered multiple episodes of the disease [56]. Thus, they are not likely to be due to chronic antipsychotic medication.

The cellular basis of gray matter volume losses in schizophrenia is not yet known, it appears that it is more likely due to the loss or disorganization of neuronal processes. Several postmortem studies have reported abnormal neuronal organization within corticolimbic structures in schizophrenic patients [51, 53]. Reduced number of neurons has been reported in the anterior cingulated cortex, nucleus accumbens, hippocampus, and thalamus from people who died with schizophrenia (6). Also, the gray matter losses in schizophrenic patients have been hypothesized to involve abnormal increases in apoptosis.

Recent research using noninvasive neuroimaging techniques, such as magnetic resonance imaging (MRI), suggests that some patients with schizophrenia show progressive losses of gray matter in the frontal and temporal lobes of the brains. In addition to this, neuroimaging studies have demonstrated anatomical abnormalities

in a network of neocortical limbic regions and interconnecting white matter tracts. Bilateral ventriculomegaly and decrease brain volume exist in medial temporal areas such as the hippocampus and amygdale [51, 55].

Some follow-up neuroimaging studies have shown a progressive ventricular enlargement in schizophrenic patients [51, 54]. The neurobiologic process of ventricular enlargement is difficult to explain, but posited mechanisms include response to medication or chronic stress, increased vascular perfusion and metabolism, increased size or numbers of neurons and glia, increased connective tissue, increased intercellular fluid, and increased dopaminergic neurotransmission.

Several investigators using MR spectroscopy (MRS) have found that schizophrenic patients have differences in the concentrations of *N*-acetyl aspartate (NAA) and various phoshomonoester (PME) and phosphodiester (PDE) moieties in specific brain regions including the temporal and prefrontal cortex. NAA is an abundant amino acid located in neuronal cell bodies and processes. PMEs are phospholipids involved in membrane synthesis, and PDEs are by-products of lipid metabolism that are believed to reflect membrane turnover. Investigators found NAA reduced in the temporal cortex, PME concentrations reduced in the prefrontal cortex, and PDEs elevated in the prefrontal cortex primarily [57]. These results are interesting and may reflect pathophysiologic processes in schizophrenia.

Accumulating evidence suggests that BDNF is involved in the pathophysiology of schizophrenia. BDNF belongs to the neurotrophic factor family and is highly concentrated in the nervous system and the serum. It plays a critical role in the development, regeneration, survival, and maintenance of the function of neurons and plasticity of multiple neurotransmitter systems. Reduced neurotrophic factor signaling could lead to both an altered development of the central nervous system and neuronal death [52, 58].

Recent studies have revealed a strong link between BDNF signals and dopaminergic (DA) function in the brain [49, 58]. Specially, BDNF is involved in the neurodevelopment of dopaminergic-related systems, interacts with the mesolimbic DA systems, and also involved in the therapeutic response to antipsychotic medications. Recent postmortem studies have shown that BDNF is reduced in the hippocampus and prefrontal cortex of patients with schizophrenia [58]. Recently, two studies revealed decreased BDNF levels in the serum of chronic schizophrenic patients [58]. Some studies have found that both atypical and typical antipsychotic drugs such as haloperidol, clozapine, and risperidone decreased BDNF concentrations in frontal, occipital cortex, and hippocampus of patients with schizophrenia [49]. Tan et al. [58] have reported that BDNF were significantly lower in medicated patients with chronic schizophrenia than in healthy control subjects. Antipsychotic treatment might have affected levels of BDNF. So, decreased BDNF in patients with schizophrenia might be responsible for the neurodegeneration due to antipsychotic drugs.

Reduced expression of BDNF and its receptor could also contribute to an enhanced susceptibility for apoptotic death in schizophrenia since this neurotrophin possesses neuroprotective properties [52]. Reduced BDNF has been reported in the prefrontal cortex from schizophrenic brains and in serum of schizophrenic patients [58]. Glutamatergic hypofunction could lead to reduced BDNF expression since activation of non-NMDA receptor (NMDAR) leads to a 10-fold increase in BDNF messenger ribonucleic acid (mRNA) content in hippocampal neurons. Also, kynurenic acid (an endogenous antagonist of glutamatergic receptors) blocks the increased BDNF mRNA content induced by the activation of glutamatergic receptors in hippocampal neurons, and thus glutamatergic hypofunction could also be related to the decreased BDNF expression. Furthermore, glutamatergic hypofunction could lead to decrease antiapoptotic signaling mediated by the Akt protein [52].

Gliosis has been reported in schizophrenia for at least 20 years [51, 52]. Many studies have tried to detect gliosis in the brains of patients with schizophrenia. However, little evidence of a gliotic reaction typical of a neurodegenerative process has been found [51]. Glial proliferation has been found in the subiculum and orbitofrontal cortex of the brains of people with schizophrenia and dementia compared to those of people with schizophrenia without dementia, independently of neuroleptic exposure. The result of this study was not significantly different from control and study samples. It suggested that a neurodegenerative process leading to gliosis could be present in patients with chronic schizophrenia [52].

Several possible mechanisms of neuronal injury are now being investigated in patients with schizophrenia [51, 52]. Excitotoxicity, for example, neurodegeneration via the overactivity of excitatory neurotransmission, is an attractive mechanism to explain neuronal injury. Since it could be initiated and/or maintained through the action of neurotransmitter systems, such as the monoamines, that have long been implicated in schizophrenia [51]. Excitotoxic process is induced by the production of dopamine-generated reactive oxygen species, including superoxide, hydroxyl radicals, and oxidized glutathione. All of which can cause pathological changes in neurons via oxidation of deoxyribonucleic acid (DNA), proteins, and lipids [49].

The release of dopamine is involved with glutamatergic neurons and NMDA receptor (NMDAR) activation. Since glutamatergic neurons in the medial prefrontal cortex project to the nucleus accumbens and reduce

dopamine release through action on metabotropic glutamate receptors (mGluR). Glutamatergic neurons also stimulate GABAergic interneurons through NMDAR. Some studies found that dopamine in striatal decreased secondary to an increased release of glutamate, which led to excitotoxic damage in the globus pallidus and substantia nigra [49].

NMDAR antagonism could also lead to neurotoxicity. Some investigators have suggested that NMDAR blockage reduces cortical inhibitory tone, thus increasing the firing rate of glutamatergic neurons leading to excitotoxic death at postsynaptic neurons through non-NMDAR. Overstimulation or blockade of glutamatergic neurotransmission in different metabolic pathways could lead to neurodegeneration in schizophrenia [52].

Another possible mechanism leading to neurodegeneration is apoptosis [49, 51] or programmed cell death, which can occur rapidly and under a number of circumstances including dopamine depletion or in the absence or decrease of BDNF. The process to apoptosis involves activation of intracellular proteases via mitochondria or tumor necrosis factor. Some studies have been hypothesized that cellular mechanisms responsible for such gray matter losses may be involved in apoptosis [51]. Apoptosis may also relate to gene expression. For example, significantly reduced content of the antiapoptotic protein Bcl-2 and increased Bax/Bcl-2 ratio (associated to susceptibility for apoptotic death) in Brodmann's area (BA) and ultrastructural changes in oligodendroglial cells suggestive of apoptotic death have been found in the brains of people who died with schizophrenia [49, 52]. Moreover, apoptosis may be induced by antipsychotic medications. For example, a single dose of haloperidol given to rats resulted in a substantial increase in apoptotic GABAergic cells in the substantia nigra and striatum within 48 h. Also, DNA fragmentation, cell shrinkage and nuclear membrane disintegration were observed in patients taking haloperidol [49].

Mitochondrial dysfunction [49, 52] may be one mechanism underlying apoptosis induced by antipsychotic drugs. A single dose of haloperidol in mice has led to inhibit complex I of the mitochondrial respiratory chain and led to oxidative stress in a number of brain areas [49]. Some investigators have suggested mitochondrial dysfunction is associated to excitotoxicity. Mitochondrial dysfunction reduces Na/K ATPase activity, increasing membrane depolarization. NMDA receptor becomes voltage activated and magnesium is extruded from the ion channel permitting calcium influx, which in excess may lead to excitotoxic death. Mitochondrial dysfunction leads in turn to dopaminergic overactivity by decreasing dopamine uptake [52].

Dopamine depletion may be another mechanism underlying apoptosis since dopamine receptor stimulation increases NMDAR activity and excitotoxicity. This mechanism could be involved in dopamine-induced nitric oxide (NO) synthesis. NO is synthesized by the enzyme NO synthase (NOS) after NMDAR activation. Some studies have found evidence for a significant reduction in NO biosynthesis in patients with schizophrenia. This result may not be caused by antipsychotic medications. Reduced NO biosynthesis may lead to some susceptibility for neuronal death because NO is associated to both neurotoxic and neuroprotective effects [52].

The effects of stress may provide a possible explanation for the neuronal structure change [52, 55]. Oxidative stress may play a role in the pathophysiology of most neurodegenerative disorders. Some studies have suggested that oxidative stress could be associated with the development of tardive dyskinesia and might be caused by antipsychotic treatment [49]. Other studies have found a reduced total glutathione content in the cerebrospinal fluid (CSF) and prefrontal cortex of neuroleptic-treated schizophrenic patients, which may reflect reduced antioxidant defense and oxidative stress [52]. It suggested the presence of oxidative stress may lead to cell death. On the other hand, oxidative stress has been associated with impaired learning and might be involved in the cognitive deficit of patients with schizophrenia.

Neurocognition is severely impaired in schizophrenia. Patients with schizophrenia appear to perform less well on most cognitive tasks and show greater levels of impairment in selected functions such as attention, working memory, verbal memory, executive functions [48, 59, 60]. Some studies have found that schizophrenic patients, who have more episodes, more severe psychotic symptoms over sustained periods, experience severe cognitive decline. Also, patients with longer duration of untreated psychosis have greater cognitive dysfunction than first-episode patients [60]. Another study found that T cell deficiency might lead to cognitive dysfunction in schizophrenic patients [61].

The evidence of neural degeneration in the pathophysiology of schizophrenic illness suggests that there may be treatment opportunities through neural protection. Neuroprotection, which refers to treatment that helps maintain central nervous system functionality in response to neurobiologic stress, may be responsible for prevention of disease progression and deterioration. Based on the neurodegeneration in schizophrenia and evidence from in vivo neuroimaging studies, it is reported that haloperidol treatment was associated with a greater rate of cortical gray matter loss than olanzapine. It suggested that olanzapine has neuroprotective effect since it might slow the progressive loss of cortical gray matter in patients with schizophrenia [51]. Also, other studies stated that haloperidol has been

associated with reactive oxygen species (ROS) generation and other neurotoxic effects [49, 52]. It leads to an increased basal glutamate concentration in the striatum and nucleus accumbens [49, 52]. It seems that typical drugs do not have good neuroprotective effects for schizophrenic patients.

In contrast to typical antipsychotics, atypical antipsychotics such as olanzapine and clozapine have shown neuroprotective properties and cognitive improvement in patients with schizophrenia [62]. Those drugs have been shown to reduce apoptosis, cell death, and to increase BDNF levels and protein levels [49]. Recent studies reported that olanzapine and clozapine have increased levels of BDNF in the brain of schizophrenic patients [62]. Olanzapine protects against methamphetamine-induced neurotoxicity and reduces apoptotic cell death induced by trophic factor withdrawal. Both olanzapine and clozapine increase Bcl-2 protein and mRNA levels in the frontal cortex and hippocampus. Bcl-2 protein is protective against neuronal death induced by several mechanisms and has been shown to decrease in the temporal cortex of brains from people who died with schizophrenia. Neuroprotective effects of atypical antipsychotics may be associated with the inhibitory effect of 5-$HI_{1A}$ receptors. Also, atypical antipsychotics such as olanzapine and clozapine appear to improve cognitive performance in schizophrenic patients [52]. Keefe et al. [63] reported that olanzapine has a beneficial effect on neurocognitive function in patients with a first episode of psychosis.

Many recent studies have yielded valuable data indicating the possibility of significant side effects of antipsychotic medications on the cellular function and structure of the brain in schizophrenia. The neurodevelopmental hypothesis has emerged over the past few years as a popular and useful approach to understanding and studying schizophrenia. Hypothesis of neurodegeneration in schizophrenia should be studied further since we only know possible mechanisms of neurodegeneration in schizophrenia, yet we do not know the etiology of neurodegeneration. Whether there are progressive brain changes over time, or there is the possibility of long-term antipsychotic drugs that induce the neurodegeneration, or it is due to genetic, environmental, and developmental factors needs to be further explored.

### 5.2 Neuroprotection as Future Therapeutic Goal in Schizophrenia

According to Lieberman, schizophrenia is a continuous neurodegenerative process as patients degenerate slowly from early "prodromal symptoms" to "psychosis" where a person is unable to function in society. Neuronal degeneration usually occurs after the onset of psychosis. It is also more difficult to treat patients who have relapsed from previous therapy. It is believed that this is due to degeneration of the neurons. Thus, it is important to have a neuroprotective agent as part of the treatment therapy at an early stage of the disease in order to slow down or prevent the neurodegeneration process. By doing so, it will improve patient outcomes and minimize the chance of relapse [64]. This opens the door to a novel mode of treatment for schizophrenia called neuroprotection. Ehrenreich defined neuroprotection as "the effort to maintain the highest possible intactness of cellular interactions/intercellular communication in the brain resulting in an overall undisturbed function [65]." The mechanism of neuroprotection is basically to prevent the deterioration of neuronal function in patients with schizophrenia. Researchers are looking at the role of atypical antipsychotics, glutamate, metabotropic glutamate receptor agonist, erythropoietin (EPO), and estrogen as future antipsychotic therapies for schizophrenia with neuroprotective effect.

As mentioned before, people with schizophrenia suffer from loss of gray matter. When compared with normal individuals, schizophrenics have more gray matter loss. Brain images showed that people with schizophrenia at a later stage have more loss in gray matter than people at the early stage [66]. According to Lieberman et al., atypical antipsychotics, such as olanzapine, have been proven to have the ability to not only slow down the degeneration of the gray matter, but they also increase gray matter in the temporal cortical after 3 months. The study also found that patients receiving atypicals has greater improvement in cognition than patients on typical antipsychotics such as haloperidol. Olanzapine has also been demonstrated to reduce neuronal loss in the hippocampus in rats treated with kainic acid [67]. In his study, Bian et al. [67a] reported that perospirone, quetiapine, and ziprasidone also protect the neurons by inhibiting the production of toxic NO generated by microglial cells. Another study conducted by Dazzan et al. [68] showed that patients taking typical antipsychotics have gray matter loss in the temporal gyrus, while those on atypicals have significant enlargement of the thalamus. Thus, atypical antipsychotics seem to have an important and promising role in neuroprotection in patients with schizophrenia.

The pathology of schizophrenia involves many neurotransmitters such as dopamine, serotonin, and glutamate. The first class of medication in treating schizophrenia targeted the dopamine pathway. This was followed by atypical antipsychotics, which targeted mainly serotonin and dopamine pathways. Recent studies are looking at the role of glutamate in the pathology of schizophrenia. It is the major neurotrans-

mitter of the cortex, limbic system, thalamus, hippocampus, and amygdala. It has been shown that schizophrenia can be caused by hypofunction of the glutamate receptors in the cortical area, specifically the NMDA receptors [69]. In the normal individual, NMDA receptors have inhibitory GABAergic neurons that normally inhibit the overproduction of dopamine in the mesolimbic dopamine pathway. With schizophrenic individuals, the GABAergic neurons are inhibited by the hypofunction of glutamate receptors, thus leading to disinheriting of glutamate. As a result of the disinhibition, glutamate receptors are stimulated to the point that it can result in glutamate excitoxicity and hypersecretion of dopamine. This theory was observed in patients abusing phencyclidine (PCP), which is an NMDA antagonist. In healthy individuals PCP induces schizophrenic signs and symptoms such as psychosis. Excessive firing of the glutamate neurotransmitter can lead to detrimental effects on neurons because too much glutamate is released. Glutamate activation is followed by the release of large quantities of sodium and calcium, allowing them to enter the neuron and initiate the chemical reactions that ultimately result in death of the neurons. Thus, glutamate receptor agonists, glutamate release inhibitors, AMPA agonists and antagonists, and ampakines are beneficial for schizophrenia and are good candidates for potential antipsychotics.

Glycine is an example of glutamate receptor agonists. The binding of glycine to its receptors located on the NMDA receptors is necessary in order for glutamate neurotransmission to occur. Therefore, increasing glycine concentration could potentially activate more NMDA receptors and reverse the hypofunction of the glutamate receptors. Studies have shown that at doses of 30–60 g/day, glycine can significantly improve negative symptoms [69, 70]. Its limitation is that glycine has poor blood–brain barrier penetration. D-serine is another glycine agonist, but it is more permeable at the blood–brain barrier than glycine. At a dose of 30 mg/kg/day in addition to neuroleptics, the combination significantly increased negative, positive, and cognitive functions. Thus, D-serine seems to be the most promising [69]. Another mechanism to increase glycine levels is by inhibiting the glycine transporter (GLY-T1). By inhibiting the GLY-T1 reuptake pump more glycine is available to bind to the NMDA receptors. Sacrcosine is a GLY-T1 inhibitor that has been shown to have positive impact on negative symptoms as well as cognition [71]. However, one study in mice showed that mice without GLY-T1 died due to respiratory depression [72].

Metabotropic glutamate (mGlu) receptors are also potential targets for the development of neuroprotective drugs. mGlu2/mGlu3 (found in the cortex, hippocampus, cerebellar cortex) and mGlu5 (found in the hippocampus, cerebellar cortex, thalamus nuclei, and spinal cord) receptors have been examined and the result seems promising [73]. Activation of these receptors results in the inhibition of glutamate release, inhibition of calcium and potassium channels, and stimulation of the formation of astrocytes. The limitations are overstimulation of mGlu5R can cause epilepsy, convulsion, and neurotoxicity, and activation of mGlu2/mGlu3 can result in the inactivation of the CREB cycles [74].

Yale University is currently recruiting patients for a randomized, double-blind, placebo-controlled study to look at the efficacy of riluzole in the treatment of refractory schizophrenia. Riluzole is currently indicated for the treatment of Lou Gehrig's disease. It is a severe and rapidly progressing neurodegenerative disease that affects neurons in the brain and spinal cord. Riluzole exerts its neuroprotective effects by inhibiting the release of glutamate, inhibiting the voltage-gated sodium channels, and inhibiting protein kinase C. Riluzole could be a promising new neuroprotective drug for patients suffering from schizophrenia as schizophrenia is also a progressing neurodegenerative disease [75]. Another class of drug that is in the early stage of clinical trials is the ampakines and CX516 belongs to this class of drug. CX516 enhances NMDA receptors indirectly through the AMPA receptors. Significant improvements in cognition, attention, and memory were seen in schizophrenic patients in two clinical studies when CX516 was combined with clozapine [69].

Erythropoietin has been widely used in the hospital setting for the treatment of anemia for many years. Not until recently has it been shown to have neuroprotective effects. Under normal conditions, its presence is low; however, when neurons are damaged or under stress, its presence is upregulated. It was hypothesized that the upregulation of EPO helps to protect the degeneration of neurons. Clinical studies have shown that erythropoietin has antiapoptotic, antioxidative, anti-inflammatory, neurotrophic, angiogenic, synaptogenic, and glutamate inhibitory properties [76]. With such promising mechanism of action, EPO could be a potential "add-on" agent for neuroprotection in patients with schizophrenia. EPO receptors are overly expressed in the hippocampus and cortex of schizophrenic patients [77]. EPO can cross the blood–brain barrier and exerts its action locally in the brain. A pilot study called Gottingen EPO-Stroke showed that patients treated with EPO have better outcomes such as less neurological loss, suffer from smaller brain lesion, and less glial damage (low S-100B levels) [78]. More importantly patients on EPO also recover to baseline faster. In a 2-year multicentered double-blind, randomized placebo-controlled study, also conducted by Ehrenriech et al. [79] demonstrated that patients on EPO as add-on have significantly better

cognitive performance than placebo. This study also showed a significant reduction in glial damage (low level of S100B) [79].

Epidemiologically, the prevalence of schizophrenia is equal for males and females. Males have earlier onset of schizophrenia than females. However, as women go through menopause, more females are diagnosed with schizophrenia than males. During menstruation or pregnancy, women experience symptoms. This is thought to be associated with a decrease in estrogen and that estrogen acts as a protective agent. Like the atypical antipsychotics, estrogen exerts its action on both dopamine and serotonin receptors. Estrogen has been shown to reduce dopamine concentration in the striatum and modulate the serotonin system by increasing the serotonin receptor transporter. In addition, it also increased NMDA receptors [80] and has antioxidant properties that prevent oxidative stress on the neurons. The overall mechanism of neuroprotection of estrogen is described in the flowchart shown in Figure 6.

The concept of neuroprotection for the treatment of schizophrenia seems to be promising. Those agents such as glycine and D-serine, which target the NMDA receptors, have the most potential in the development of a new class of antipsychotics. Atypical antipsychotics have been shown to be an effective treatment for schizophrenia; however, there are people who relapse from this therapy alone. An "add-on" agent such as EPO might be beneficial in preventing neuron damage due to uncontrolled schizophrenia. Estrogen also has promising results in the neuroprotection of schizophrenia. It acts on all three main neurotransmitters that are involved in the pathology of schizophrenia. Since most of the data are derived from animal studies, more studies in humans are necessary in order to determine the safety and efficacy. This promising novel class of medication will hopefully help schizophrenic patients from deteriorating neurologically as well as symptomatically.

### 5.3 Newer Hypotheses and Future Drugs

As discussed before, hyperdopaminergic brain function is currently the most prominent hypothesis used in explaining the etiology of schizophrenia. Dopamine hypothesis has several lacunae and fails to explain the lack of effect of dopamine antagonists in treating the negative symptoms of schizophrenia. Current research

**Figure 6** Neuroprotection by estrogen. (Reproduced with permission from [81].)

has several explanations for the lack of effect of dopamine antagonists and has put forward newer hypotheses to better explain the diseases and the effects of drugs. Although some of these have been referred to in previous sections, to put in perspective, we are summarizing them below.

***Glutamate Hypothesis*** One of the most notable alternative hypotheses is the glutamate hypothesis, which states that schizophrenia is produced by the hypogultaminergic activity in the brain. Glutamate is an excitatory neurotransmitter in the CNS. The glutamate hypothesis took roots from the observation that the glutamate antagonist PCP produces symptoms, especially hallucinations, of schizophrenia. One interesting thing about glutamate antagonism is that it produces both positive and negative symptoms as opposed to just positive symptoms produced by dopamine overactivity. PCP acts somewhat selectively on a glutamate receptor subtype known as NMDA (*N*-methyl-D-aspartate) receptors. These receptors are excitatory in function and PCP probably inhibits the release of neurotransmitters mediated by NMDA receptors. Other antagonists at NMDA receptors such as ketamine, dexoxadrol, and MK-801 have also been reported to produce psychosis-like symptoms [82–84]. Another supporting finding for glutamate theory is that glycine, an NMDA agonist, reverses PCP-induced symptoms in rodents and makes patients with schizophrenia better [85]. However, caution has to be exercised in interpreting these results since there are a few findings in the literature that contradict the glutamate hypothesis.

***Cholinergic Role in Schizophrenia*** It is known that many people with schizophrenia smoke heavily, indicating that nicotine might relieve some of the symptoms of this condition. This observation also implies the dysfunction of the cholinergic system in schizophrenia. One of the earliest publications relating cholinergic system and mania came out in 1972 [86]. Cholinergic muscarinic receptors were found to be mediating the extrapyramidal effects of several first-generation antipsychotics [87]. In a postmortem study in humans, a higher cholinergic activity, indicated by choineacetyltransferase (ChAT) enzyme, was found in the hippocampus, caudate, putamen, and nucleus accumbens of schizophrenia patients compared to controls [88]. In another clinical study, therapeutic antagonism was shown between anticholinergic agents and neuroleptics [89]. The negative symptoms of schizophrenia have been attributed to the overactivity of the cholinergic system [90]. The same group showed a differential effect of anticholinergic drugs on schizophrenia, where these drugs increased the positive symptoms significantly, while reducing negative symptoms [91]. Another interesting observation related to cholinergic involvement is that chronic treatment in rats with haloperidol resulted in reduction of ChAT activity and a visual decrease in the immunoreactivity in neurons as well as in their processes in the striatum and the hippocampus [92]. This might also indicate the cholinergic mediation in the therapeutic effect of haloperidol. Hippocampal nicotinic receptors have been shown to be decreased in schizophrenia in a postmortem study [93]. Several recent studies involving humans and animals have indicated that altered expression and function of the $\alpha_7$-nicotinic cholinergic receptor may be responsible for the auditory sensory gating deficit characterized in schizophrenia patients and their relatives as diminished suppression of an auditory-evoked response to repeated stimuli [94]. Atypical, but not typical, antipsychotic drugs have been shown to increase cortical acetylcholine release without an effect in the nucleus accumbens or striatum [95]. An agonist at the $\alpha_7$-nicotinic receptor, 3-2,4 dimethoxybenzylidene anabaseine (DMXBA), has been shown to enhance auditory sensory gating in animal models [96]. Therapeutic doses of clozapine, olanzapine, and, to a lesser extent, quetiapine are associated with clinically relevant anticholinergic activity indicating a role in their therapeutic efficacy. All these findings point to a definite involvement of cholinergic system in the pathophysiology of schizophrenia. However, there are no drugs available to treat schizophrenia that act by modulating cholinergic system.

***New Drugs in the Pipeline*** Although we have come a long way from chlorpromazine type of drugs, there still need to be several refinements to be done to develop an ideal antipsychotic drug without/minimal significant side effects (which may never be possible practically). There were recent efforts to modify the drug delivery of existing drugs to improve the therapeutic index. Risperidone's long-acting formulation was shown to be well tolerated [97] and, of course, improved therapeutic levels in schizophrenic patients who are generally poorly compliant. Sustained release quetiapine from AstraZeneca (Seroquel) is undergoing clinical studies currently and preliminary data indicates significant improvement in improved symptoms associated with schizophrenia (measured by positive and negative syndrome scale [PANSS]) and an increase in time to psychiatric relapse, when administered once a day (http://www.astrazeneca.com/pressrelease/5310.aspx).

Apart from delivery modifications, there are a few targets that have shown promise in preclinical studies and concept-of-proof studies. Prominent among them is the $\alpha_7$ neuronal nicotinic receptor. Data from several studies suggest a link between the $\alpha_7$ neuronal nicotinic acetylcholine receptor (nAChR) and brain disorders,

including schizophrenia. A novel molecule (PNU-120596), developed by Pfizer, works as a powerful positive allosteric modulator of $\alpha_7$-nicotinic receptors. Systemic administration of PNU-120596 in animals improved the auditory gating deficit caused by amphetamines, a model that mimics circuit level disturbance associated with schizophrenia [98]. Another selective partial $\alpha_7$-nicotinic agonist, DMXBA, has been shown to improve these learning and memory deficits and deficits in sensory inhibition in rodent models. Clinical trials with DMXBA also demonstrated improved sensory inhibition in 12 schizophrenia patients and showed improvement in several subtests of the RBANS learning and memory assessment instrument. Thus these data strongly suggest that $\alpha_7$-nicotinic activators may prove useful in treating some of the symptoms of schizophrenia [99]. Glutamate receptor (NMDA) modulators also have shown some promise in preclinical trials, but there is no clinical data yet to prove their usefulness in humans.

## 6 CONCLUSION

The pharmacotherapy of schizophrenia has evolved significantly from chlorpromazine to second-generation antipsychotics. Although scientific research could get rid of the extrapyramidal side effects of first-generation antipsychotics, there are newer side effects that came with the atypical antipsychotics. With the advancement of molecular biology and biomedical sciences, we could hope that more molecular targets for treating schizophrenia with fewer side effects will be available in the near future.

# RADIOPHARMACEUTICALS AND MEDICAL IMAGING: DEVELOPMENT OF RADIOIMMUMOCONJUGATES FOR RADIOIMMUNOIMAGING AND RADIOIMMUNOTHERAPY OF MALIGNANT DISEASES

Gang Niu and Xiaoyuan Chen

*Molecular Imaging Program at Stanford (MIPS), Department of Radiology and Bio-X Program, Stanford University School of Medicine, Stanford, California*

## 1 INTRODUCTION

Radioisotopes have been applied to detect and treat malignant diseases for a long time. Radiopharmaceuticals are generally classified as either being diagnostic or therapeutic according to their application. As shown in Figure 1, a radiopharmaceutical can be considered to have three components: (i) the targeting carrier, (ii) the radionuclide, and (iii) a linker moiety [1]. A perfect radiopharmaceutical would, after intravenous administration, travel via the bloodstream to the target cells, where it would efficiently bind only with cell surface or intracellular counterparts or interact solely with the desired molecular pathway. Any radioligand that did not reach the desired target would be rapidly excreted from the body so that the only radioactivity remaining in the body would be that localized to the target site. The development of radiopharmaceuticals has followed closely behind the advances made by the relevant disciplines such as particle physics, chemistry, radiochemistry, radiopharmacy, and biology. Radioimmunopharmaceuticals or radioimmunoconjugates (RICs) are using antibody (Ab) or antibody derivatives as targeting carriers, taking advantage of the specific binding between antibody and antigen. In this chapter, we will discuss several aspects of RIC development and their application in radioimmunoimaging (RII) and radioimmunotherapy (RIT) for malignant diseases, including lymphoma, prostate cancer, colon cancer, and breast and ovarian cancers.

## 2 RADIONUCLIDES

Radionuclides function as beacons in RII and killing agents in RIT. For imaging purpose, γ-ray and positron emitters will be used, while β-particle emitters, α-particle emitters, and Auger and Coster-Kronig electron emitters will be considered for RIT. A number of factors need to be considered when selecting appropriate radionuclides for RII and RIT, including emission characteristics, physical half-life, cost, availability, and linkage chemistry. The radionuclides evaluated in preclinical and clinical RII and RIT studies have been summarized in several reviews [1, 2].

As one of the predominant factors for determining a radionuclide's suitability for RII and RIT, the physical half-life should be comparable to the time needed for

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*

**Figure 1** Radiopharmaceutical is typically composed of a radionuclide, a carrier that is/contains a targeting ligand, and a linker between the carrier and the radiolabel.

the radiolabeled antibody or fragments targeting the tumor (typically 2–4 days for intact Abs and 2–6 h for Ab fragments). In general, radiolabeled intact Abs have been used in tumor detection and treatment planning, as well as in RIT, whereas the application of Ab fragments has been restricted to tumor detection only. Although the use of shorter-lived radionuclides (with half-lives of hours) for RII with Ab fragments is an option, the kinetics of intact Abs demand the use of long-lived radionuclides (half-lives of days) to allow imaging at later time points for obtaining maximum information. Based on their half-lives, radionuclides such as $^{94m}$Tc ($t_{1/2} = 0.87$ h), $^{68}$Ga ($t_{1/2} = 1.13$ h), $^{18}$F ($t_{1/2} = 1.83$ h), and $^{99m}$Tc ($t_{1/2} = 6.02$ h) are better suited for use in combination with Ab fragments. Radionuclides with longer half-lives including $^{64}$Cu ($t_{1/2} = 12.7$ h), $^{86}$Y ($t_{1/2} = 14.7$ h), $^{76}$Br($t_{1/2} = 16.2$ h), $^{124}$I ($t_{1/2} = 78.4$ h), and $^{89}$Zr ($t_{1/2} = 100.3$ h) are suitable for imaging of Ab fragments as well as intact Abs. The half-lives of these radionuclides offer an advantage with respect to the logistics of radiolabeling and transportation but a potential disadvantage with respect to the radiation burden to the patient, especially when coupled to compounds with long biologic half-lives, such as intact Abs. For RIT purposes, Abs labeled with shorter-lived radionuclides will have suffered significant decay of activity before maximum uptake in the tumor.

The applicability of a radionuclide is also dependent on the availability of methods to obtain it in pure and sufficient amounts, the time period available for transportation and labeling, the availability of procedures for its stable coupling to an Ab with maintenance of the Abs in vivo biodistribution characteristics, and identification of undesirable components in its decay scheme that could compromise image quality and quantification accuracy. For example, the presence of prompt single γ-photons will cause spurious true coincidences during positron emission tomography (PET) study, such as $^{86}$Y, $^{76}$Br, and $^{124}$I. High positron energy will result in an intrinsic resolution loss ($^{94m}$Tc, $^{68}$Ga, $^{76}$Br, and $^{124}$I), and the presence of radionuclidic impurities or radioisotopes of the same element generated during cyclotron production such as $^{94m}$Tc will disturb the labeling process and reduce labeling yield [2].

Radionuclides usually used for therapy produce intermediate and long-range β emissions, which have a traveling range of several millimeters to a centimeter in tissue. The range in tissue of these β emissions allows for a potential "cross-fire" effect, where despite heterogeneous distribution of the radiolabeled antibody, radiation can reach not only the antibody-targeted cell but also neighboring nontargeted cells. Some therapeutic radionuclides such as $^{131}$I also have γ-ray emission, which may be useful for scintigraphic imaging and for determinations of in vivo localization of the radiopharmaceutical and evaluation of dosimetry. Besides $^{131}$I ($t_{1/2} = 8.4$ days), $^{186}$Re ($t_{1/2} = 3.8$ days), and $^{90}$Y ($t_{1/2} = 2.67$ days) are two commonly used therapeutic radionuclides. $^{90}$Y is a useful radionuclide for RIT due to its energetic β emissions ($E_{max} = 2.3$ MeV), ready availability at moderate cost, and absence of γ emissions, allowing outpatient RIT. Its half-life of 64 h is comparable to the uptake and residence time of many antibodies on the tumor [3]. Other radiometals, such as $^{67}$Cu, $^{188}$Re, and $^{177}$Lu also have suitable β emissions for therapy, but availability may limit their widespread use in clinical trials.

Compared with β particles, the high linear energy transfer (LET) characteristics of α particles make it possible to perform much localized irradiation while preserving the surrounding tissues. Moreover, cell toxicity can be obtained with only a few disintegrations at the cell surface. On the other hand, the cross-fire effect in α-RIT is limited, owing to the short path length of these particles. These physical characteristics appear to be very suitable for targeting isolated cells of hematological malignancies, such as multiple myeloma and leukemia. For instance, the targeting of interleukin-2 (IL-2) receptors using specific CD25 antibodies coupled with $^{213}$Bi ($t_{1/2} = 45.6$ min) have proved to be more efficient than the use of $^{90}$Y in the treatment of T-cell leukemia [4]. Multiple myeloma can be efficiently targeted by α-RIT using an anti-CD138 antibody (BB4 MAb) [5, 6]. A synergistic effect has been documented between α-RIT and chemotherapy using paclitaxel in multiple myeloma cell lines. Owing to the short half-life of $^{213}$Bi, $^{212}$Bi ($t_{1/2} = 60.6$ min), or $^{211}$At ($t_{1/2} = 7.0$ h), the number of injected radioactive atoms is extremely limited [7]. Such a limit imposed by short half-life of radionuclides has prompted using antibody fragments such as $F(ab')_2$ or diabodies to improve the biodistribution [8].

## 3 ANTIBODY AND ANTIBODY FRAGMENTS

### 3.1 History of Antibody Development

The majority of Abs produced in mammals has a molecular weight of approximately 150 kDa. The Ab molecule is composed of pairs of polypeptide chains, light and heavy, that are linked by disulfide bridges. Specifically, the $IgG_1$ molecule consists of two variable light chains ($V_L$) and two variable heavy chains ($V_H$), two constant light chains ($C_L$), and six constant heavy chains (Fig. 2). The antigen-binding region of the Ab consists of the $V_L$, $V_H$, $C_L$, and $C_{H1}$ domains, also known as the Fab portion of the antibody. The Fc portion consists of the $C_{H2}$ and the $C_{H3}$ domains and is involved in a number of immune response effector functions and involved in antibody clearance from circulation. Effector functions that have been associated with the Fc portion include complement-mediated cytotoxicity (CMC) and antibody-dependent cellular cytotoxicity (ADCC). The whole immunoglobulin is bivalent because it has two antigen-binding sites, one on each "arm" of the Y-shaped molecule.

Over the last several decades, there have been continued refinements in the production and the design of antibodies used for RII and RIT. Initial efforts used polyclonal antibodies, which were produced by a collection of antiserum after immunization of a given species, such as rabbit, to a specific antigen. In 1975, Kohler and Milstein [10] developed the hybridoma technique, which allowed for the production of monoclonal antibodies (mAbs). The selected hybridoma would produce large quantities of a specific mAb with single specificity allowing for the rapid expansion of clinical trials evaluating radiolabeled mAbs to a variety of tumor-associated antigens. These antibodies provided new approaches for the RII and RIT of cancers and metastases [11].

However, the clinical utility of rodent mAbs is limited by their immunogenicity and often inefficient secondary immune functions. These issues also hinder the application of murine antibodies in repetitive imaging. Humanized antibodies are commonly created by transplanting the antigen-binding segments, known as complementarity determining regions (CDRs), from rodent antibodies into human antibodies [12]. The localization of antibody in tumors following passive transfer of antibodies is governed by a complex series of events involving extravasation of antibody and its diffusion into the tumor tissue. The deposition of an antibody is also dependent on the tumor mass and its location, the binding affinity to tumor-associated antigens, the degree of expression of the relevant antigen, and its stability on tumor cells [13]. The large molecular size of intact antibodies leads to prolonged serum half-life. Intact antibodies also take a long time for maximal dose deposition in the target tissue, due to the slow diffusion from the vasculature into the tumor [14]. Moreover, Ab intratumoral diffusion is limited by its size to a penetration rate of about 1 mm every 2 days, potentially resulting in heterogeneous deposition in the tumor [15]. Tailoring the antibody molecules by enzymatic digestion, antibody fragments $F(ab)'_2$ and Fab′ may allow more rapid elimination from the blood and normal tissues (except kidneys), due to the smaller size than intact antibodies [16]. However, these antibody fragments are tedious to prepare and not readily reproducible [17]. Antibody engineering has made it possible to tailor antigen-binding domains into a single polypeptide with

a much smaller size than intact immunoglobulin. A single-chain Fv (scFv) recombinant protein for a given monoclonal antibody can be prepared by connecting genes encoding for heavy-chain and light-chain variable regions at the deoxyribonucleic acid (DNA) level by an appropriate oligonucleotide linker. The resulting translation product forms a single polypeptide chain with a linker bridging the two variable domains [18]. Compared with intact parental antibody (150 kDa), scFv (28 kDa) for a given immunoglobulin exhibits faster clearance kinetics and deeper tumor penetration; however, the absolute dose deposition of scFv is much lower [19]. This is primarily due to its monovalent binding nature, which results in lower functional avidity. The degree and specificity of tumor localization of scFv can be improved by increasing the affinity for its corresponding antigen. Divalent and multivalent scFvs (diabodies or tribodies) can result either from the spontaneous dimerization or covalent association of two or more monovalent scFvs [20, 21]. With their bivalent or multivalent binding, they exhibit better tumor deposition than their scFv counterparts, yet clear faster from the circulation than intact antibodies because of their smaller molecular size (55 kDa for diabody and 80 kDa for tribody) [22]. These recombinant antibody fragments with di- or multivalent binding with intermediate molecular weight (60–120 kDa) are a compromise between slow-clearing high-localizing immunoglobulins and fast-clearing low-localizing monovalent scFvs [23]. The fusion proteins of scFv with the hinge region and CH3 domain of immunoglobulin molecule are called minibodies. The hinge region facilitates dimerization mediated by disulfide bond formation and imparts flexibility to the antigen-binding domain. With the molecular weight of 80 kDa, minibodies persist longer than diabodies in the serum, hence allowing higher dose deposition in the tumors [24]. The structure and approximate molecular weight of IgG antibody, engineered antibody fragments, and Affibody is shown in Figure 2.

### 3.2 Affibody and Small Antibody Mimics

Affibody molecules are small nonimmunoglobulin affinity ligands based on a 58-amino-acid Z-domain scaffold, derived from one of the IgG-binding domains of *staphylococcal* protein A [25]. Randomization of 13 amino acid positions in the binding surface of this domain scaffold has been used to construct combinatorial phagemid libraries, from which affibody molecules bound to desired target molecules can be selected by phage display [26, 27]. The affibody molecule $His_6$-$Z_{HER\text{-}2/neu:4}$ was demonstrated to bind with nanomolar affinity (approximately 50 n$M$) to the HER-2-ECD molecule at a different site than the humanized antibody trastuzumab. $^{125}$I-labeled $His_6$-$Z_{HER\text{-}2/neu:4}$ affibody made by indirect radioiodination using *N*-succinimidyl-*p*-(trimethylstannyl) benzoate (SPMB) showed specific binding to native HER-2 overexpressed on the SKBR-3 tumor cell line [28, 29]. The bivalent form of the affibody ligand, $(Z_{HER\text{-}2:4})_2$ has a molecular weight of 15.6 kDa and an apparent affinity ($K_D$) against HER-2 of 3 n$M$, which is approximately the same as trastuzumab. Due to its small size, $^{125}$I-$(Z_{HER\text{-}2:4})_2$ affibody was primarily excreted through the kidneys, which caused extremely high kidney accumulation. The second-generation HER-2-specific affibody molecule ($His_6$-$Z_{HER\text{-}2:342}$), obtained by a single-library affinity maturation, bound HER-2 with a $K_D$ of 22 p$M$. Gamma camera imaging with $^{125}$I-$His_6$-$Z_{HER\text{-}2:342}$ showed clear, high-contrast visualization of HER-2-expressing xenografts in mice as early as 6 h postinjection. Due to increased affinity, the uptake for $Z_{HER2:342,}$ compared to the parental $Z_{HER2:4}$ monomer, improved by 2.03, 3.94, and 24.29 times at 1, 4, and 24 h, respectively, with a tumor uptake of ~ 9% injected dose (ID)/g at 4 h [30]. The relatively small size of affibody molecules also enables a direct chemical peptide synthesis to link chelators directly and site specifically at high yields [31].

Two CDRs, $V_H$CDR1 and $V_L$CDR3, through a cognate framework region ($V_H$FR2), yield small anibody mimetics. These mimetics retain the antigen recognition of their parent molecules but have a superior capacity to penetrate tumors. The antigen recognition abilities of these approximately 3-kDa mimetics surpass those of comparable fragments lacking the framework region. In vivo activities of the mimetics suggests that the structural orientation of their CDRs approximates the conformation of the CDRs in the complex of the parent antibody with antigen [32]. Currently, there is no RIC available based on this small antibody mimetics.

### 3.3 Antibody Affinity

Antibody affinity is defined as the strength with which an antibody molecule binds an epitope, that is, antigenic determinant. Mainly, the nocovalent interactions between antibody and its epitopes, including ionic interactions such as attraction of opposite charges on amino acids, hydrogen bonds and hydrophobic interactions, contribute to affinity, which can be quantified by determining an association constant, $K$. Abs with binding constants less than $10^8\,M^{-1}$ are not likely to be useful for drug targeting or tumor imaging [33]. Affinity maturation of antibodies is often associated with increased in vitro biological potency [34]. Evidence for increased affinity prolonging the tumor retention of radiolabeled antibody comes from studies using B72.3, an mAb with specificity for the pancarcinoma antigen TAG-72. The tumor targeting of B72.3 was compared to a series of

higher affinity second-generation mAbs, each reactive with a different epitope of TAG-72. The second-generation mAb CC49 ($K_d = 6 \times 10^{-11}$) localized human tumor xenografts in athymic nude mice better than did the lower affinity molecule B72.3 ($K_d = 2 \times 10^{-9}$) [35]. Through recombining, engineering, and phage display screening, recombining antibodies, Fab fragments, and mimetics with enhanced affinity could be obtained [9]. In a striking example, the cumulative effect of many small structural alterations resulted in a single-chain antibody fragment (scFv) with 1800-fold increase in fluorescein-binding affinity compared with its high affinity wild type [36]. By creating mutant scFv gene repertoires and displaying their encoded proteins on the surface of filamentous bacteriophage, affinity mutants of a human scFv (C6.5) that bind to an epitope on the extracellular domain of HER-2 has been created [37]. The scFv mutants span a 320-fold range of affinities. After iodination, biodistribution studies were performed in severely compromised immune deficient (SCID) mice bearing human ovarian SKOV-3 tumors. At 24 h after injection, tumor retention of the highest affinity scFv was 7-fold greater than that of a mutant with 320-fold lower affinity [37].

However, there is another contradictory theory about the potential impact of affinity on the successful targeting and retention of mAb in tumors. Fujimori et al. [38] has postulated that high-affinity mAb will not successfully penetrate deeply into tumors due to a binding site barrier effect in which interaction with the first antigen encountered at the periphery of the tumor will block further diffusion of the mAb into the tumor. Support for this hypothesis comes from the observation that intravenous (IV) administration of the mAb $^{131}$I-D3, specific for the chemically induced L10 carcinoma line ($K_a = 1.6 \times 10^{10}\,M^{-1}$), to guinea pigs bearing intradermal L10 tumors, resulted in peripheral binding to antigenic patches, whereas $^{125}$I-labeled control mAb was uniformly distributed throughout the tumor [39]. Moreover, even though localized better in animal models, in subsequent clinical trials, the second-generation mAb CC49 failed to display improved tumor retention over that observed for B72.3 [40]. Blindly increased affinity, however, might approach an upper limit of antigen-binding affinity beyond which further increases in affinity do not enhance tumor localization [41].

The relationship between the antigen-binding affinity of an antibody and its in vivo properties, with tumor targeting being the most widely studied property, is still unclear. With a panel of HER-2-specific scFvs, it has been demonstrated that the antigen-binding affinity of an antibody influences tumor localization. A threshold affinity ($K_d$) of $10^{-7}$–$10^{-8}\,M$ was required for specific tumor localization of scFvs, with uptake reaching a plateau at a $K_d$ of $10^{-9}$–$10^{-11}\,M$. The lowest affinity scFv had the most uniform distribution throughout the tumor, whereas the highest affinity scFv was found mainly in the perivascular region of the tumor [42]. There may exit an upper limit of antigen-binding affinity beyond which further increases in affinity do not seem to be beneficial for tumor localization. Conversely, overly high binding affinity will limit tumor penetration, which is consistent with the "binding site barrier," as described by Weinstein and colleagues [38]. In addition, simple dimerization of a low-affinity scFv can lead to considerably greater tumor localization than can be achieved by the more time-consuming process of scFv affinity maturation [43]. It has also been reported that no significant difference in tumor uptake was found between both anti–carcinogenic antigen (CEA) antibodies, despite their 10-fold difference in affinity [39]. The marked effect of antigen-binding affinity on the in vitro and in vivo activities of antibodies supports the idea that affinity also has a considerable impact on the clinical utility of antibodies. Whether there is an optimal antigen-binding affinity for antibodies remains unexplored. Antibody internalization may also affect the tumor uptake and retention of RIC. In a human colon cancer LS174T mouse tumor model, biodistribtution study showed that the internalizing antibody was accumulated more rapidly compared with the noninternalizing antibody. However, the maximum uptake showed no statistical difference [44].

## 4 ANTIBODY LABELING

### 4.1 Halogens

Initially, halogen radionuclides, especially iodine, were used in RII ($^{123}$I) and clinical RIT ($^{131}$I) trials because it was readily available, and labeling methods were well established, with iodine usually covalently linked to the antibody through tyrosine residues [45]. For direct iodination, it has been noted that even under very mild oxidizing conditions, some proteins lose a portion of their biologic activity, most likely from oxidation of thiols. For Abs, the loss of activity might mainly result from iodination of a tyrosine that was involved in the binding. Moreover, iodination of tyrosine residues or agents with a similar structure tends to be recognized and dehalogenized in vivo by deiodinases. In addition, if bound to tumor antigen and internalized into the cell, as in some tumor systems, further dehalogenation is possible. Free iodine usually deposits in the thyroid, salivary glands, and stomach [46]. Radiohalogenation of proteins using indirect methods has been investigated, including optimization of labeling chemistry and biological characterization of some labeled conjugates. Two indirect radiohalogena-

tion methods were used, representing two different labeling principles: activated ester of benzoic acid [47] and the derivative of *closo*-dodecaborate anion [48] (Fig. 3). The nonphenolic linker as well as the borate-halogen moiety probably prevent dehalogenation. The negative charge of the potential catabolic products of *closo*-dedecaborate anion might trap radiohalgodens intracellularly [48]. Antibodies can be conjugated with various *closo*-dodecaborate(2-) containing ligands. DABI, a derivative of *closo*-dodecaborate, [(4-isot hiocyanatobenzylammonio)undecahydro-*closo*-dodecaborate], has been successfully radioiodinated with a high yield (93–95%) and coupled to an antibody. In vivo data revealed that $^{125}$I-DABI-mAb conjugates yielded a low thyroid uptake with no accumulation compared with a direct labeling antibody [48]. Compared with direct labeling, indirect labeling usually generates lower yields and is more time-consuming and complicated.

**Figure 3** Structures of the three different $^{125}$I-antibody conjugates used. (A) Directly labeled mAb, (B) indirectly PIB-labeled mAb, and (C) indirectly DABI-labeled mAb [48].

### 4.2 Coppers

Most radionuclides, especially radiometals, need to be labeled to Abs by indirect labeling methods with bifunctional chelates (Fig. 4). Bifunctional chelators contain, in addition to the metal chelating unit, a linkage and conjugation group for attachment to the tumor-seeking moiety, that is, Abs in RICs. Conjugation of chelates to antibodies is performed via electrophilic conjugation groups (activated esters), attached to a linker, which can be a phenyl group or a short peptide in addition to the phenyl group (Fig. 4). For copper ($^{67}$Cu and $^{64}$Cu) labeling, several chelating agents are available. The prototype is the macrocyclic chelator 1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (TETA) developed for copper labeling by the Meares group [49]. TETA is a bifunctional carboxylated cyclam-14 derivative that complexes copper rapidly at ambient temperature to maintain protein function. The TETA ligand, as well as a number of other 4N macrocycles, forms copper(II) complexes of high thermodynamic stability, which also exhibit high kinetic stability under physiological conditions. Despite the high kinetic stability of the TETA copper complex, transchelation of Cu from the complex to these proteins in the liver has been observed in vivo with $^{67}$Cu-TETA-labeled antibodies and $^{64}$Cu-TETA-labeled octreotide [50]. Cross-bridged cyclam ligands were synthesized with increased reduction potential in order to lessen the electrochemical reduction of Cu(II) to Cu(I), which is believed to affect the dissociation of copper from the complex [51]. However, complexation of copper with these ligands requires elevated temperatures (75°C), which is not optimal for postconjugation labeling of proteins, and these ligands, therefore, may be more suitable for peptide labeling. We have labeled with various

**Figure 4** Representative chelators for radiometal labeling.

peptides and antibodies with $^{64}$Cu using bifunctional 1,4,7,10-tetraazacyclododecane-N,N′,N″,N‴-tetraacetic acid (DOTA) as chelating agent and performed PET imaging in animal models [52–54]. We have found that the $^{64}$Cu-DOTA complex is very stable when attached to macromolecules or nanoparticles, with the majority of the $^{64}$Cu label remaining intact after incubation in full mouse serum at 37°C for 24 h [55].

Besides the in vivo stability of the used copper complexes, their charge and lipophilicity also have an important impact on the biodistribution of Cu-labeled immunoconjugates. Macrocyclic copper complexes bearing different charges and exhibiting different degrees of lipophilicity, such as $^{67}$Cu-TETA or -DO3A complexes, lead to distinct differences in biodistribution when used for labeling of antibody fragments. The chelates (TETA, DOTA, DO3A) with carboxylic groups (p$K_a$ values in the range of 2–5) attached to the nitrogen donor atoms are very hydrophilic. Indeed, clearance of radioactivity from the kidneys was found to be much faster in the case of antibody fragments substituted with negatively charged hydrophilic copper complexes [56]. The extent of conjugation of chelates to the antibody has to be optimized in every case in order to ensure that immunoreactivity is retained after conjugation. It also has to be considered that even when no effect on immunoreactivity is observed, substituting the protein with too large a number of ligands can lead to significant changes in biodistribution and increased activity in the liver [57].

### 4.3 Yttrium-90

Numerous chelating agents for $^{90}$Y have been investigated for RIT, primarily derivatives of the acyclic chelator diethylenetriaminepentaacetic acid (DTPA) [58] and the macrocyclic chelator DOTA [59]. Yttrium complexes of the acyclic chelators are not as kinetically stable as those of DOTA [60]. The extraordinary stability of the yttrium-DOTA complex minimizes the loss of $^{90}$Y to bone, a target organ of the radionuclide itself. However, the radiolabeling yields of $^{90}$Y-DOTA immunoconjugates are 50% typically, which is much less than that of $^{90}$Y-DTPA immunoconjugates (often in yields of >90%). Improved yields are needed to reduce the cost of therapy with $^{90}$Y-DOTA immunoconjugates and to minimize the exposure of radiolabeling personnel to radiation [59].

### 4.4 Chelator Antibody Ratio

Most indirect labeling of antibody is through the usage of a bifunctional chelator. The ideal condition is that after chelator conjugation, the antibody still keeps its immunoreactivity and kinetics in vivo. Several studies aimed at illustrating the effect of chelator/antibody ratio (c/a) on immunoreactivity and biodistribution have been performed. With mAbs labeled with $^{153}$Sm through the bifunctional DTPA molecule, rapid blood clearance and liver accumulation was observed in rats when 20 chelate groups were coupled per mAb [61]. A similar phenomenon was observed for mAbs labeled with $^{67}$Cu through the 14N4 macrocycle in mice [62]. To determine the maximum chelator: antibody ratio (c/a) of 2IT-BAT-Lym-1 at which functional integrity is preserved, immunoconjugates with a c/a of 1.3–23 were prepared and examined by radioimmunoassay and competitive antigen binding versus lightly iodinated Lym-1. Conjugates with a c/a up to 5 exhibited no loss of immunoreactivity, and conjugates with a c/a up to 11 retained 75% or greater immunoreactivity relative to unmodified Lym-1. Tumor uptake declined with increasing c/a, but the effect was insignificant at c/a 2.1 and 4.3. The biodistribution data suggested a negative correlation between c/a of 2IT-BAT-Lym-1 and uptake in tumor and a positive correlation between c/a and uptake in liver. Conjugates of c/a 4–5 were found to be optimal for the preparation of RIC of high specific activity with minimal, if any, loss of functional integrity [57]. In another study, magnesium based chalators (MAGs) were used as chelators to label mAb with $^{99m}$Tc and $^{186}$Re for RII/RIT. Immunoreactivity of mAbs remained nearly intact upon coupling of up to 20 $^{186}$Re-MAG3 groups. However, there was a serious alteration of the pharmacokinetic behavior of conjugates containing more than eight $^{186}$Re-MAG3 groups on average. There was a strong correlation between the $^{186}$Re-MAG3:MAb E48 molar ratio and blood clearance [63]. The reason for higher liver uptake may be due to nonspecific binding of the radiolabel to the mAb and the presence of aggregates [64]. The mechanism behind the rapid blood clearance of mAbs containing too many metal-chelator groups is not yet known. Some authors addressed that both the increased fraction of immunoconjugate with both binding sites inactivated and strong anodal shifts in isoelectric point (*p*I) of immunoconjugates contributed to the decline in tumor uptake and increased liver uptake [65]. In addition, the tolerance of metal-chelator conjugation seemed to be varying with different antibodies [57].

### 4.5 Biodistribution and Dosimetry Evaluation

Besides lesion detection, another main application of RII is to localize the biodistribution of RIC and calculate the dosimetry for effective RIT. Some therapeutic radionuclides, such as $^{131}$I, have γ-ray emission, which will facilitate imaging and following dosimetry

evaluation. However, some therapeutic radionuclides are pure β or α emitters, including $^{90}$Y, need another γ emitter to perform RII.

Biodistribution of $^{90}$Y for dosimetry calculations is typically obtained by imaging, using the surrogate radiometal $^{111}$In because $^{90}$Y does not emit photons. $^{111}$In has an almost identical half-life as $^{90}$Y, emits 2 γ rays of 171 and 245 keV, and can be readily incorporated into the same metal chelating agents as $^{90}$Y. For these reasons, $^{111}$In has been considered an excellent analog for $^{90}$Y. For example, the Food and Drug Administration (FDA) approved RIC ibritumomab tiuxetan (Zevalin, BiogenIDEC) labeled with $^{90}$Y to treat non-Hodgkin's lymphoma (NHL), and it is required that $^{111}$In-ibritumomab tiuxetan be used to produce images of the tumor and normal organs for dosimetry and biodistribution studies [66]. However, it has been reported that $^{111}$In-trastuzumab did not parallel the uptake of $^{86}$Y-trastuzumab in the bone and thus may not accurately predict the level of $^{90}$Y accumulation in the bone for clinical RIT applications [67, 68]. Subtle differences in radionuclide retention of the metal chelating agents used for $^{111}$In and $^{90}$Y mAb labeling can result in a differential release between the two radiometals. With less stability than $^{111}$In-DTPA, transchelation of $^{90}$Y from the chelating agent can result in a higher dose to the bone and bone marrow, which would not be anticipated from biodistribution data derived from $^{111}$In, possibly leading to underestimation of the radiation dose to bone marrow. Thus, quantitative information offered by PET through $^{86}$Y radiolabels could enable more accurate absorbed dose estimation for $^{90}$Y RIT [68]. A HER-2-specific antibody, trastuzumab, has been labeled with $^{86}$Y using 2-(4-isothiocyanatobenzyl) DTPA (SCN-CHX-A-DTPA) as chelator to assess the therapeutic potential of $^{90}$Y-trastuzumab in a human ovarian carcinoma (SKOV-3) model [69]. It has also been reported that $^{99m}$Tc-mAb conjugates showed a similar pharmacokinetic behavior as $^{186}$Re-mAb conjugates and can thus be used to predict the localization of $^{186}$Re-labeled mAbs and make dosimetric predictions in individual patients [63].

## 5 PRETARGETING

All pretargeting procedures use a modified mAb that not only recognizes a target antigen but also permits a second component to bind to it specifically. By separating the targeting steps, the mAb does not need to be treated with reagents used for conjugation to a suitable radionuclide, which ensures its immunoreactivity is uncompromised. The unlabeled modified mAb is administered first, distributes throughout the body to bind to the cells expressing the target antigen, eventually clearing from other tissues. The second component, which is radiolabeled, is then administered and, ideally, localizes at sites where the modified mAb has accumulated. If the second component has higher permeation, clearance, and diffusion rates than those of an mAb, the radionuclide will localize more rapidly to the tumor and higher tumor selectivity can be achieved compared to a directly radiolabeled IgG [70]. Pretargeting methods can be divided into several types such as biotin–avidin (or streptavidin) involved or a bispecific monoclonal antibody (bsmAb) involved pretargeting (Fig. 5) [71]. All radionuclide-pretargeting methods require the modified mAb to be cleared adequately from the blood before the injection of the radiolabeled effector; otherwise, a sizable portion of the effector would bind to it in the blood, taking on its pharmacokinetic and distribution properties. Regardless of the pretargeting method used, each has been shown in animal models and in patients to be highly efficient targeting procedures, with improved therapeutic properties as a result of the enhanced tumor/blood ratios [71, 72].

Two distinct methods for pretargeting using the avidin/streptavidin–biotin method have evolved. In one, StAv is conjugated to an antitumor IgG, making a conjugate with a molecular size of approximately 170–220 kD [73]. Because of their large size, a clearing agent is needed to remove excess StAv–IgG from the blood before the radiolabeled biotin injection; otherwise, the radiolabeled biotin, with its ultra-high affinity for StAv, would be bound tightly to the StAv conjugate in the circulation [74]. Though low concentration of biotin is present naturally in serum and tissues, this system has been used effectively in patients without efforts to reduce endogenous biotin levels. However, the presence of biotinidases in the serum may cleave the biotin–radionuclide conjugate [75]. The second StAv–biotin pretargeting configuration uses biotin-conjugated antitumor IgG as the modified mAb [76]. To make use of radiolabeled biotin instead of radiolabeled StAv or avidin, glycosylated avidin is injected first to remove the biotin–IgG conjugate from the blood. Within 30 min, nonglyscosylated StAv is given. As StAv enters the tumor, it binds tightly to any biotin–IgG it encounters. After allowing time for the avidin and StAv to clear from the body, radiolabeled biotin is given. With four biotin-binding arms, ample sites are available on the StAv within the tumor to foster the bridging of the radiolabeled biotin to the tumor-bound biotin–IgG [71].

A bispecific antibody (bsmAb) binds both to a target antigen as well as the radiometal–chelate complex of the effector molecule [77]. Unlike approaches based on avidin/streptavidin that rely on a clearing step, bsmAb pretargeting simply delays giving the radionuclide until the bsmAb has cleared sufficiently from the blood. Due to its smaller size, bsmAb clears more quickly than the

larger IgG-based conjugates. BsmAb pretargeting relies on a radiolabeled effector that bears two haptens capable of binding to the antihapten binding arm of the bsmAb. This technique, called the affinity enhancement system (AES), improves the uptake and retention of the radiolabeled hapten-peptide [78]. The major advantage for a bsmAb approach is the ability to use humanized antibodies that will have a lower immunogenicity than the foreign streptavidin or avidin proteins. In contrast to the monovalent chelate–radiometal complex, a bivalent structure would be bound more stably at the tumor site, presumably because the divalent hapten-peptide could be cross-linked by two adjacent bsmAbs [79]. The hapten portion of the bsmAb pretargeting system is responsible for binding to the antihapten arm of the bsmAb. Initially, the hapten was a radiometal-binding chelate, such as DTPA, which could also be loaded with a radiometal, such as $^{111}$In. Two DTPAs could be joined together synthetically by a short (e.g., usually 2–4 amino acids) peptide. The uptake of the radiolabeled hapten-peptide appears to be highly efficient from a number of perspectives. Because the hapten-peptide uptake achieves it maximum accretion within minutes [80], not only is the total radiation dose delivered to the tumor higher, but it is delivered at a much higher dose rate [81]. For imaging, this has resulted in tumor/blood ratios that are 40-fold higher than a directly radiolabeled Fab fragment [80]. In addition, the hapten-peptide can be radiolabeled at higher specific activities than a directly radiolabeled antibody, which would bring more radionuclide to the tumor per unit mass of hapten-peptide delivered.

The antigen marker for a pretargeting system being targeted must be accessible and should stay accessible in sufficient concentration to allow time for the untargeted bsmAb to clear from the blood. A targeted substance that internalizes quickly after being bound by the bsmAb would not be a good candidate for a pretargeting application, and, therefore, direct targeting would be preferred. With antigen being present in the blood, a directly radiolabeled antibody would likely result in higher accretion of radioactivity in the liver or spleen after forming complexes with the circulating antigen. In contrast, as long as the unconjugated bsmAb–antigen complexes are effectively removed before the administration of the radiolabeled hapten-peptide, efficient targeting of the tumor would be obtained with pretargeting strategy [82].

## 6 RII AND RIT OF MALIGNANT DISEASES

### 6.1 Lymphoma

The T101 monoclonal antibody recognizes a pan-T-cell antigen present on normal T cells and is also found in high concentrations in cutaneous T-cell lymphoma. Gamma-camera imaging using $^{111}$In-T101 has been performed in 11 patients with advanced disease to detect sites of metastatic cutaneous T-cell lymphoma [83, 84]. $^{111}$In-labeled MoAb directed against eosinophil peroxidase could localize lymphomas infiltrated by eosinophils [85, 86]. With $^{99m}$Tc-labeled a murine monoclonal antibody LL2 (EPB-2) Fab′, a number of previously unknown tumor sites were revealed by LL2-radioimmunodetection despite normal morphologic imaging results [87]. However, it has also been reported that radioimmunodetection with $^{99m}$Tc-labeled CD19 mAb is inferior to computed tomography (CT) and gallium-67 scanning in the diagnosis of patients with B-cell non-Hodgkin's lymphoma [88].

The CD20 antigen is an excellent target because it is expressed on pre-B cells and mature B cells, including up to 95% of B-cell NHL. Moreover, CD20 does not shed, modulate, or internalize. More importantly, it is absent from stem cells and plasma cells [89]. Rituximab, a chimeric monoclonal antibody directed against the CD20 antigen, was the first monoclonal antibody approved by the FDA for the treatment of NHL [90]. Rituximab immunotherapy is now routinely used in the treatment of low-grade NHL as an up-front single agent [91] or as part of combination chemotherapy [92]. By further improving the efficacy, anti-CD20 RIT has enhanced the survival not only of patients with large-cell NHL but also of those with follicular NHL.

Ibritumomab tiuxetan (Zevalin, BiogenIDEC) and tositumomab (Bexxar, GlaxoSmithKline) are both FDA-approved RICs for the treatment of patients with CD20 positive, follicular, non-Hodgkin's lymphoma. Zevalin contains ibritumomab, a murine anti-CD20 antibody, and tiuxetan, an MX-DTPA linker–chelator. Ibritumomab tiuxetan can be coupled with either $^{111}$In for tumor imaging and dosimetry or with $^{90}$Y for therapy. Bexxar is a murine monoclonal antibody that binds to CD20 and is radiolabeled with $^{131}$I for RIT. In contrast to $^{90}$Y-ibritumomab tiuxetan, the therapeutic dose of tositumomab is based on dosimetry. Patient-specific dosing is necessary because of the interpatient differences in spleen size, tumor burden, and the metabolism and renal excretion of $^{131}$I [93].

To address whether the anti-CD20 RICs really offered any advantages over the respective unlabeled anti-CD20 antibodies, $^{90}$Y-ibritumomab tiuxetan was compared to rituximab in patients with relapsed CD20$^{+}$ NHL who had never received rituximab [94]. The complete response (CR) rate was 30% in the $^{90}$Y-ibritumomab tiuxetan group and 16% in the rituximab ($P = 0.04$) group. The estimated median time to progression (TTP) was similar in both groups. However, the estimated time to next therapy for patients with nontransformed histology was significantly longer for $^{90}$Y-ibritumomab

tiuxetan patients (17.8+ months; range: 2.1–21.7+) than for rituximab patients (11.2 months; range: 1.3–19.0+) ($P = 0.040$). RIT for relapsed indolent NHL produces an overall response rate (ORR) of approximately 60–80% and a CR in 15–30% of patients. The RICs produce a higher response rate than their respective cold unlabeled antibody. RIT has a high response rate (approximately 75–80%) in rituximab-refractory patients.

### 6.2 Breast and Ovarian Cancer

As early as 1967, $^{131}$I-labeled antibodies to human fibrinogen have been used to localize mammary carcinoma and 12 of 17 lesions were visualized [95]. Consequently, various antibodies have been labeled with $^{123}$I, $^{131}$I, or $^{111}$In for breast or ovarian cancer localization or lymph node metastases [96–98]. Following IV administration, $F(ab')_2$ fragments cleared from the blood more rapidly than the intact IgG [98]. The mean tumor uptake of $^{111}$In-labeled HMFG1 $F(ab')_2$ fragments at 24 h was significantly higher than the intact IgG, but at 48 h there was no difference. Lymph node metastases showed higher antibody uptake than the corresponding primary tumors. Successful localization was observed in approximately 50% of the primary and metastatic lesions with no false-positive results. A monoclonal antibody MA5 reacted with greater than 95% of the primary and metastatic lesions and recognized a cell surface antigen. In 17 patients with breast cancer, $^{111}$In-labeled MA5 monoclonal antibody visualized bone lesions, primary tumors, soft tissue recurrences, and lung metastases larger than 3 cm diameter [99]. RII has been performed to image bone or lymph node metastases of breast cancer [100, 101]. $^{99m}$Tc-labeled antigranulocyte monoclonal antibody BW 250/183 (AGMoAb) scans in 32 patients showed bone marrow defects in 25/32 (78%) patients; bone invasion was subsequently confirmed in 23 (72%) patients [101]. Two of antiaberrant MUC-1 mucin epitopes mAbs, BrE3 and m-170, which show high levels of staining on most breast cancer biopsy specimens, have provided excellent tumor targeting in imaging studies [102].

Human epidermal growth factor receptor 2 (HER-2) is a cell membrane surface-bound receptor tyrosine kinase. Overexpression of HER-2 has been detected in up to 30% of breast and ovarian cancers [103]. The first HER-2-specific imaging study was performed in 1991 with a class-switched murine monoclonal antibody SV2-61r that recognizes the extracellular domain of HER-2 [104]. Monoclonal antibody ICR12 is a rat IgG2a with high affinity for an external epitope on the protein core of HER-2 (human epidermal growth factor) [105, 106]. In patients selected by IHC staining, planar and single photon emission computer tomography (SPECT) imaging with $^{99m}$Tc-ICR12 showed good tumor localization in both the primary lesion and regional node metastases [107]. Scintigram with $^{99m}$Tc-labeled another murine monoclonal antibody CIBCgp185 against HER-2 also showed high radiolabel uptake by the human breast cancer BT474 tumor tissue in mice [108]. PET imaging with $^{124}$I-labeled ICR 12 has been performed, and MDA-MB-361 tumor xenografts in nude mice of 6 mm diameter could be visualized at 24, 48, and 120 h after probe injection [109].

The murine mAb 4D5, directed against the extracellular domain of HER-2, is a potent inhibitor of growth of human breast cancer cells that overexpress HER-2 [110]. By inserting the CDRs of mAb 4D5 into the framework of a consensus human IgG, a recombinant humanized anti-HER-2 monoclonal antibody called trastuzumab has been developed. Trastuzumab is the first monoclonal antibody approved by the FDA for use in women with breast cancer who have tumors that overexpress HER-2 protein. Previously unidentified lesions were visualized in 13 of the 15 patients on the $^{111}$In-DTPA-trastuzumab scintigraphs, and the overall detection rate of tumor lesions was 45% at the single-lesion level [111]. The trastuzumab Fab was radioloabeled with $^{111}$In after DTPA derivatization, and the binding affinity was not significantly decreased with a dissociation constant ($K_d$) that changed from 14–36 to 47. $^{111}$In-trastuzumab Fab localized specifically in HER-2-positive BT-474 human breast cancer xenografts in athymic mice (compared with $^{111}$In-HuM195 anti-CD33 Fab). BT-474 tumors as small as 3–5 mm in diameter could also be imaged as early as 24 h postinjection [112]. A direct comparison between Fab and full-length antibody has been reported with $^{111}$In-labeled trastuzumab and a trastuzumab-derived Fab (Fab4D5) through DOTA conjugation [113]. In a spontaneous mammary tumor model in MMTV/HER-2 transgenic mice, $^{111}$In-DOTA-Fab4D5 showed early tumor localization at 2 h with little retention followed by rapid accumulation in the kidneys by 6 h, which indicated a rapid washout of Fab from the tumor after initial accumulation. $^{111}$In-DOTA-trastuzumab was slow to accumulate in tumors and slow to clear from normal tissues, and significant tumor deposition was achieved by 24 h. The peak tumor uptake for Fab was around 12% ID/g at 16 h postinjection and around 45% ID/g at 24 h postinjection for trastuzumab. By introducing an albumin binding sequence to Fab4D5, a bifunctional molecule AB.Fab4D5 capable of binding albumin and tumor antigen HER-2 simultaneously has been developed [114]. Vallabhajosula et al. [115] labeled $F(ab')_2$ fragment of trastuzumab with a positron emitter $^{68}$Ga ($t_{1/2} = 68$ min) to assess the degradation of HER-2 by 17-allylaminogeldanamycin (17-AAG), a heat shock

protein 90 (Hsp90) inhibitor. Taking advantage of the fast blood clearance of $F(ab')_2$ and quick decay of $^{68}Ga$, they repetitively imaged HER-2 expression at 24-h intervals. Based on the microPET quantification, HER-2 expression was reduced by almost 80% in the animals 24 h after 17-AAG treatment [115]. In a follow-up study, tumor response to 17-AAG treatment were assessed by $^{68}Ga$-DOTA-$F(ab')_2$-trastuzumab and $^{18}F$-FDG PET. Within 24 h after treatment, a significant decrease in HER-2 was measured by HER-2 PET, whereas $^{18}F$-fludeoxyglucose (FDG) PET uptake was virtually unchanged. The 17-AAG-treated animals had a reduced uptake of $^{68}Ga$-$F(ab')_2$-trastuzumab that lasted until 5 days after treatment, although notable growth inhibition occurred only by 11 days after treatment. The $^{18}F$-FDG PET imaging data revealed no significant differences in $^{18}F$-FDG metabolism between treated and control group at any of the time points examined. This indicates that HER-2-PET with $^{68}Ga$-DOTA-$F(ab')_2$-herceptin could provide accurate information for tumor early response to 17-AAG treatment [116].

By creating mutant scFv gene repertoires and displaying their encoded proteins on the surface of filamentous bacteriophage, affinity mutants of a human scFv (C6.5) that bind to an epitope on the extracellular domain of HER-2 has been created. Tumor retention of the highest affinity scFv was 7-fold greater than that of a mutant with 320-fold lower affinity at 24 h after injection [37]. Divalent and multivalent scFvs (diabodies or tribodies) can result either from the spontaneous dimerization or covalent association of 2 or more monovalent scFvs [19, 20]. Compared to a monovalent 741F8 Fab fragment of approximately the same size, the divalent bismalimidohexane-linked 741F8 $(sFv')_2$ showed significantly greater tumor localization. This suggests that the increased avidity of the $(sFv')_2$ was a factor in its improved tumor retention [17, 117]. Instead of direct iodination by the chloramine-T method, 741F8-1 $(sFv')_2$ has also been radioiodinated by using *N*-succinimidyl *p*-iodobenzoate (PIB), a protein radioiodination acylating agent. The PIB method involves the coupling of the radioiodine to a nonphenolic aromatic ring of the PIB reagent that is not susceptible to in vivo dehalogenase activity. The $^{125}I$-PIB complex is then conjugated to lysine residues on the scFv through the formation of an amide bond [118]. This method leads to high retention of the radiolabel on the protein and results in prominent tumor localization in tumor-bearing SCID mice [119]. However, dehalogenation of the radiotracer resulted in significant uptake of iodine by the thyroid and stomach. C6.5 diabody has also been labeled through a water-soluble form of Bolton–Hunter reagent sulfosuccinimidyl-3-(4-hydroxyphenyl) propionate (SHPP) to avoid dehalogenaton. Animals receiving SHPP-labeled diabody contained lower levels of free iodine in their blood than animals receiving iodogen-labeled diabody. However, the SHPP methodology decreased the immunoreactive fraction of the diabody about 2-fold compared with the iodogen-labeling methodology. Moreover, PET images of animals injected with $^{124}I$-SHPP-C6.5 diabody exhibited an overall increase in background signal due to residualization of the SHPP moiety [120].

Breast-cancer-targeted RIT has been performed in animal models first and $^{131}I$-labeled monoclonal antibody BW 495/36 showed a high tumor dose accumulation and significant reduction in tumor diameter with 42 days postinjection [121]. RIT with $^{131}I$-labeled ICR12 in athymic mice bearing MDA-MB-361 human breast cancer xenografts showed growth inhibition for >24 days at a dose of 600 μCi/mouse [105, 122]. RICs targeting to HER-2 are attractive for RIT because of the relationship of this target to very aggressive breast cancers. Trastuzumab has been used in RIT for tumor control after being labeled with β-particle emitters such as $^{131}I$ and $^{186}Re$ and α-emitter $^{90}Y$ [123, 124].

Besides HER-2, several antigen targets have proven effective for targeting metastatic breast cancer [125]. The L6 cell surface antigen, which is highly expressed on lung, breast, colon, and ovarian carcinomas, is a 24-kDa surface protein containing 3 hydrophobic transmembrane regions [126]. RIT with $^{131}I$-ChL6 provided biologic enhancement. By binding vascular endothelium, the resulting complement activation by L6 MAb increased tumor uptake of the subsequently delivered RIT [127]. An infusion of 100–200 mg of nonradioactive ChL6-saturated endothelium antigens allowed subsequently administered $^{131}I$-ChL6 to reach extravascular tumor. Activation of complement on the endothelium was associated with increased vessel permeability and uptake of $^{131}I$-ChL6 by tumor. Multiple infusions of $^{131}I$-ChL6 to 13 women with metastatic breast cancer showed that 6 of these patients had clinically measurable tumor responses; 4 had partial response [128].

RIT has been performed in breast cancer patients using T84.66, a murine $IgG_1$ with high specificity and affinity for CEA [129]. Using PBSC after radiological imaging technology (RIT) with $^{90}Y$-DTPAcT84.66, the 6 patients treated (15–22.5 mCi/m$^2$) had temporary but measurable therapeutic responses, although the maximum tolerated dose was not reached [130]. Several mAbs react with aberrant MUC-1 mucin epitopes upregulated on breast cancer. MAb to both the MUC-1 peptide core and immature sugar residues have been studied in RIT trials of breast cancer [99, 131]. Pharmacokinetics, dosimetry, and therapy trials of RIC to these epitopes in metastatic breast cancer have been well described [129]. BrE-3 to MUC-1 core peptide

epitope, in a dose escalation study as $^{90}$Y-MX-DTPA BrE-3, decreased measurable disease in 50% of patients after a single $^{90}$Y-MAb dose [132]. A single, higher dose of $^{90}$Y BrE-3 and PBSC also resulted in objective partial responses in 50% of the patients, but Abs against the mouse mAb, human antimouse antibody (HAMA), developed rapidly in most patients, so that additional therapy doses were not administered [132]. Humanized BrE-3 as $^{90}$Y MX-DTPA-hBrE-3 has been used in a dose escalation protocol with PBSC. Of 4 patients with measurable disease, 2 partial response, 1 mixed response, and 1 stable disease were reported. Anti–MUC-1 MoAb 170H.82 (m-170), against a synthetic asialo GM1 terminal disaccharide related to the Thonsen–Friedereich disaccharide, demonstrated 90% staining of 99 metastatic breast cancer biopsy specimens [125]. $^{111}$In/$^{90}$Y-DOTA-peptide-m170 has been studied in breast cancer patients and compared with $^{111}$In/$^{90}$Y-2ITBAD- m170 to evaluate the effect of a radiochelate linkage that can be catabolized in the liver. Both RICs showed excellent tumor targeting, and the new cathepsin degradable peptide linkage resulted in an improved tumor to liver radiation dose by 30%. However, PBSC support was again needed to deliver effective tumor therapy [61]. Two mAbs, B72.3 and CC49, to the cancer-related glycoprotein TAG-72, have been extensively studied for RIT in breast cancer and ovarian cancer [133]. Recently, combined-modality radioimmunotherapy (CMRIT) has been performed in human breast animal model with $^{90}$Y-radiolabeled humanized anti-Lewis Y hu3S193 monoclonal antibody and paclitaxel. CMRIT displayed significant improved efficacy over single-modality therapies [134]. In another CMRIT study, paclitaxel was combined with $^{90}$Y-DOTA-776.1, a monoclonal antibody prepared against the human ovarian cancer antigen CA125. Results indicated a synergistic antitumor effect on the growth of OVCAR-3 xenografts [135]. The heterogeneity of tumor antigens expression may be an obstacle of RIT and therapeutic efficacy for ovarian cancer treatment will be enhanced by the combined targeting of TAG-72, MUC1, and CA125 [136]. However, It was found that in patients with recurrence in epithelial ovarian cancer receiving intraperitoneal consolidation treatment with yttrium-90-labeled murine HMFG1, there is no improvement in overall survival [137].

### 6.3 Prostate Cancer

In 1983, Goldenberg et al. [138] first demonstrated that a prostate-associated marker could be targeted and imaged by Abs was the use of rabbit Abs against prostatic acid phosphatase (PAP) labeled with $^{131}$I. PAP is an enzyme produced by the prostate. It has been found in increased amounts in men who have prostate cancer [139]. With $^{111}$In labeled an anti-PAP MoAb (PAY-276), RII resulted in a tumor detection rate of 15% in 10 patients with prostate cancer [140]. Besides PAP, several other prostate-cancer-specific antigens have been used as target for detection of prostate cancer lesions and metastasis. These antigens include prostate-specific antigen (PSA) [141] and prostate-specific membrane antigen (PSMA) [142].

PSMA is a surface protein highly expressed on prostate cancer cells compared with other tissues [143]. 7E11.C5 is a murine monoclonal antibody specific for PSMA. An $^{111}$In-7E11.C5 (Prostascint, Cyt-356, capromab pendetide; Cytogen Corp., Princeton, NJ) has been approved by the FDA as a diagnostic agent for prostate cancer [144]. In a patient population of 40, $^{111}$In-CYT-356 immunoscintigraphy detected bony metastases in 21 of 38 patients (55%) [143]. It also has been applied to detect sites of occult prostate cancer and assess the pelvic lymph nodes [145, 146] and helpful in the detection of occult recurrent carcinoma after radical prostatectomy [147]. In another study, ProstaScint imaging result was found to be not as good as the rate of increase of PSA in assessing the response to salvage radiation therapy [148]. Though the epitope on PSMA recognized by 7E11.C5 has been determined to be the first 6 amino acids from the N-terminal, expressed on the cytoplasmic side of the plasma membrane, uptake and labeling of PSMA by fluorescient isocyanate (FITC)-labeled 7E11. C5 in viable cells in vitro has been observed. This is a major basis for the effectiveness of the 7E11.C5 antibody during in vivo imaging applications with $^{111}$In-labeled antibody (ProstaScint, Cyt-356) [149].

The treatment of metastatic prostate cancer with RIC was initiated by Meredith et al. [150] with $^{131}$I-labeled CC49 mAb to TAG 72.3. The majority of these patients experienced pain relief at radiation doses calculated to be greater than 25 Gy, representing a 20-fold increase over the whole-body radiation dose. The CYT-356 mAb has also been labeled with $^{90}$Y for systemic RIT of disseminated prostate cancer following failed radical prostatectomy. However, there was no therapeutic effects observed in a dose escalation trial [151]. The J591 monoclonal antibody is one of the newer generation of antibodies that have been identified for therapeutic purposes based on their recognition of and avidity for extracellular epitopes [152]. Milowsky et al. [153] initially reported a phase I trial using $^{90}$Y-labeled humanized J591 mAb in which 29 patients with androgen-independent prostate cancer were treated and 2 patients experienced objective disease responses. An α-particle therapeutic, $^{312}$Bi conjugated to this mAb through a chelating agent, *N*-[2-amino-3-(*p*-isothiocyanatophen-yl)propyl]-trans-cyclohexane-1, 2-diamine-*N*,*N*′,*N*′,*N*″,*N*‴-pentaacetic acid, reduced PSA levels and increased tumor-free survival in mice with human prostate cancer xenografts [154].

Although MUC-1 targets in breast cancer have been extensively studied over the last two decades, immunohistopathologic studies in prostate cancer have only recently been performed and have demonstrated upregulated and hypoglycosylated MUC-1, providing epitopes for targeted therapy [155]. The implications of these observations have been corroborated by excellent targeting of $^{111}$In/$^{90}$Y-2IT-AD-m170 mAb in prostate cancer patients. Calculated tumor doses ranged from 2 to 20 Gy with PSA responses and bone pain relief [156]. Initial CMRT with this same RIC and paclitaxel in prostate cancer has also shown PSA responses along with measurable tumor response but with the need for PBSC [155].

### 6.4 Colon Cancer

The first reported radioimmunoscintigraphy was performed in 1974 with human colon carcinoma grafted into nude mice using $^{131}$I-labeled antibodies to CEA [157]. A following study in 52 colorectal carcinoma patients and 15 patients with other types of cancer showed that 34 of 63 colorectal carcinoma tumor sites had significant accumulation of antibody, whereas none of the 20 sites of other cancer types gave positive results. $F(ab')_2$ fragments of the mAb gave a slightly higher percentage (61%) of positive results than did intact mAbs (51%) [158]. Gamma camera, SPECT, and PET imaging have been performed with anti-CEA antibodies and antibody fragments conjugated with corresponding radionuclides, namely $^{131}$I, $^{111}$In, and $^{124}$I, respectively [159–161]. RII using anibodis against Tag-72 [162], fibroblast activation protein (FAP) [163] and sialosyl-Tn antigen in mucin [164], and the tumor-associated antigen Lewis Y oligosaccharide [68] have been performed in human colon cancer animal models or patients with colon cancer.

A clinical testing of a bsmAb pretargeting method for cancer imaging reported successful localization of colon cancer metastases in the liver using an $^{111}$In-chelate complex given 5 days after the administration of an unlabeled anti-CEA antichelate bsmAb [165]. A bsmAb reacting with both the adhesion molecule CD44V6, a tumor-associated antigen upregulated in the colon and a low-molecular-weight Ga chelater labeled with positron emitter $^{68}$Ga (hapten). In human colon carcinoma-bearing nude mice, multistep immunoscintigraphy with bsmAbs showed an initial tumor uptake approximately of 15.5% ID/g [166]. In another study, the first antibody arm of the bsmAb recognized CEA and the secondary arm againsts a histaminyl-succinyl-glycine (HSG) structural subunit. The bsAbs were prepared as Fab′ × Fab′ conjugates using chemical cross-linking methods and as bispecific diabodies using recombinant DNA technologies. An HSG-bivalent hapten conjugate bearing the macrocyclic ring chelating agent 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid (DOTA) was radiolabeled with $^{68}$Ga or $^{67}$Ga. High tumor-to-normal tissue ratios of this system were found at 1–6 h after injection of the $^{67}$Ga-labeled bivalent hapten peptide [167]. With the similar construct labeled with $^{124}$I, tumor uptake measured at necropsy was 3- to 15-fold higher and tumor-to-blood ratios were 10- to 20-fold higher than those for $^{124}$I-Fab′ at 1 and 24 h, respectively. Tumor visualization with $^{18}$F-FDG at approximately 1.5 h was also good but showed substantially more uptake in several normal tissues [168].

Response rates from clinical trials of RIT in colon cancer have been pretty low. Therapy with the human immunoglobulin G4 chimeric version of the mAb $^{131}$I-ch-B72.3, an $IgG_1$ that recognizes a mucinlike colon cancer associated antigen, in 12 patients resulted in a high incidence of HAMA [169]. Using another target for colorectal cancer RIT, the A33 antigen, a transmembrane glycoprotein of the immunoglobulin superfamily [170], 23 patients were treated with escalating doses of $^{131}$I-A33 MAb, which demonstrated variable uptake in normal bowel and no objective responses [171]. The NR-LU-10 pancarcinoma mAb (NeoRx Corp., Seattle, WA) was also studied in colorectal cancer patients using a pretargeting scheme and a streptavidin conjugate of the Ab. Twenty-five patients treated with a single dose (110 mCi/m$^2$) of $^{90}$Y-DOTA–biotin had a response rate of 8%, and 4 patients had stable disease with freedom from progression for 10–20 weeks [8].

Among 119 tumors in 93 patients with CEA-expressing cancers that underwent radioimmunotherapy with the $^{131}$I-labeled IgG, anti-CEA antibodies NP-4 ($K_a = 10^8 M^{-1}$) or MN-14 ($K_a = 10^9 M^{-1}$), its humanized form hMN-14, as well as the anticolon-specific antigen-p (CSAp) antibody, Mu-9, tumor uptake appeared to be the most important dose-determining factor. No significant difference in tumor uptake was found between both anti-CEA antibodies, despite their 10-fold difference in affinity. Since an inverse logarithmic relationship between tumor size and antibody uptake was found for both anti-CEA antibodies, anti-CEA antibodies seemed to prevail in colorectal cancer patients having minimal disease [39]. This has also been demonstrated in animal models [172]. Behr et al. [173] reported responses in patients refractory to 5-fluorouracil but with small-volume metastatic disease (<3 cm) or patients in an adjuvant setting after metastatic liver resection. Treatment consisted of a single injection of 60 mCi/m$^2$ of humanized anti-CEA mAb, $^{131}$I-hMN-14. The objective response rate in 19 assessable patients was 16% and an overall response rate of 58% (partial, minor responses) with a mean duration of 9 months. Seven of the 9 patients given adjuvant RIT remained disease free

after follow-up of up to 36 months. Five patients with stabilized disease were retreated at the same dose and 2 of 4 assessable patients obtained a partial response. In moving toward CMRIT, studies by Buchegger et al. [174] showed that RIT with external-beam radiation was efficient as an adjuvant after surgery. Clinically, 6 patients with limited liver metastases from colorectal cancer were treated with RIT using 20 mCi $^{131}$I-labeled anti-CEA F(ab′)$_2$ combined with external-beam radiation of 20 Gy to the liver. Although reversible bone marrow and liver toxicity were observed, 3 patients had stable disease and 1 had a partial response.

## 7 OUTLOOK AND PERSPECTIVES

RII and RIT have played important roles in lesion localization and treatment, especially those with refractory malignant diseases. To further improve the efficacy of diagnosis and therapy, the challenges such as the selection of antibody ligand and radioisotope, bioconjugation and immunoreactivity, metabolic stability, and in vivo kinetics of the RICs all need to be optimized. All the improvements and refinery of RICs are centered on the three important components, which are radionuclides, chelators, and antibodies. Besides emission characteristics and half-life, several practical concerns should be considered when selecting the appropriate radionuclides, including their availability within an academic or commercial setting, the chemical processes required for their coupling to the targeting carrier, and the biodistribution of the radionuclide in the biological tissues and its decay chain.

For clinical application, site-specific, homogenous, reproducible, and easy radiolabeling is desirable. However, the most commonly used targeting agents are usually modified at multiple and randomly distributed sites by using modification chemistries based on amine, thiol, or tyrosine-reactive reagents. Thus, the resulting targeting molecules are heterogeneous with various degrees of modification. By using synthetic chemistry of HER-2-specific affibody molecules, the chelators can be introduced site specifically [29, 30, 175]. Site-specific radiolabeling and imaging for relatively small biomolecules such as VEGF [176] and scFv [177] have been reported. The relative big molecules such as anti-CEA diabody (55 kDa) also has been reported to be site specific and labeled after cysteine modification [177]. However, the optimal strategy for intact antibody site-specific labeling remains to be worked out. ROI analysis techniques currently used for imaging quantification need to outline the tumor region on images. The continuing development of SPECT/CT, PET/CT and PET/MRI will provide more accurate tumor outlining based on the anatomical images acquired by CT or MRI [178].

RII may be applicable to therapy response monitoring in addition to lesion localization and provide guidance to RIT. For example, HER-2 is one of the critical client proteins for Hsp90, and HER-2 level inside tumors declines dramatically upon heat shock protein 90 inhibitor, 17-AAG treatment. HER-2 degradation during 17-AAG treatment could be visualized and quantified by $^{68}$Ga-HER-2-PET [115]. More importantly, HER-2 PET is an earlier predictor of tumor response to 17-AAG therapy than $^{18}$F-FDG PET [116]. Recently, our group labeled anti-EGFR mAb with $^{64}$Cu to noninvasively monitor the EGFR degradation, upon

**Figure 5** (**A**) MicroPET images of PC-3 tumor-bearing nude mice at 4 and 24 h after intravenous injection of $^{64}$Cu-DOTA-cetuximab with or without 17-AAG treatment, and (**B**) PC-3 tumor uptake of $^{64}$Cu-DOTA-cetuximab as quantified from microPET scans.

17-AAG treatment through microPET imaging. The results showed that quantitative PET imaging of EGFR expression can detect the early response to 17-AAG treatment in prostate tumors (Fig. 5) [179]. Histone deacetylase (HDAC) is capable of regulating gene expression through diverse mechanisms, including modulation of the histone code and acetylation of many nonhistone proteins [180, 181]. HDAC inhibitors are a structurally diverse group of drugs that show preclinical and clinical promise as cancer therapeutics [182]. HDAC inhibitors, for instance, can selectively reduce HER-2 or EGFR expression by repressing the promoter and accelerating the decay of cytoplasmic transcripts [183]. RII for HER-2 or EGFR may also be useful to monitor the therapeutic response of HDAC inhibitors.

In conclusion, RII and RIT have made a great contribution to both preclinical studies and clinical applications. Along with the development of more specific antibodies, more suitable radionuclides, and more advanced imaging and therapeutic apparatus, better tumor lesions detection and treatment will be accomplished. At the same time, broader application of this technology to the management of cancer can be anticipated.

# THERAPEUTIC DRUG DEVELOPMENT FOR KIDNEY DISEASES

Mitchell H. Rosner, Joshua King, and Peter Monteleone
*Department of Medicine, University of Virginia Health System, Charlottesville, Virginia*

## 1 INTRODUCTION

Diseases that affect the kidney can be thought of in terms of the functional compartment that is affected by the pathogenic cause. These compartments include the renal vasculature, glomeruli, renal interstitium, renal tubules, and urinary collecting system. In each of these compartments, processes can be acute or chronic in nature and can lead to severe disease that would require some form of renal replacement therapy (hemodialysis, peritoneal dialysis, or kidney transplantation). Current therapeutic agents for kidney disease are limited and for the most part are not specifically targeted to pathogenic pathways. Given the epidemic of chronic kidney disease (CKD) (estimates are that over 8 million people in the United States have an estimated glomerular filtration rate less than 59 mL/min) [1], there is an urgent need for therapeutic agents that target this problem. Furthermore, in those patients with CKD, management of the complications associated with this disease state such as anemia and metabolic bone disease need to be effectively managed to avoid serious complications. Finally, in those patients who advance to end-stage renal disease, therapies to improve the outcomes of renal transplantation are needed.

This chapter will explore drug development across the spectrum of kidney disease. This ranges from acute kidney injury (AKI) to specific causes of chronic kidney disease such as polycystic kidney disease. Drugs to effectively manage the complications of CKD are also discussed. Finally, in each section, common obstacles to drug development for this disease state are discussed.

## 2 DRUG DEVELOPMENT FOR ACUTE KIDNEY INJURY

Acute kidney injury is due to a variety of conditions and has serious consequences. There are numerous definitions of AKI, but in general this term refers to the acute deterioration in renal function as manifested by rises in serum creatinine and fall in urine output. Clinically, this leads to impairment in the excretion of waste products and fluid and in the extreme the need for dialysis. Using large databases of U.S. hospitalizations over the past 10–15 years, there is evidence for a marked increase in the incidence of AKI [2, 3]. This, in part, reflects the increasing comorbidity and age of patients suffering AKI. It is widely recognized that AKI leads to high morbidity and mortality in hospitalized patients. While there may be evidence that morality rates are decreasing, [2, 3] they remain unacceptably high, and there is an urgent need for effective therapy [4].

Except for a few isolated studies, the vast majority of animal and clinical studies have yet to conclusively demonstrate the benefit of pharmacological treatment for AKI. Table 1 summarizes potential factors that have contributed to the lack of success of human studies. Table 2 describes novel pharmacological therapies on the horizon for the treatment.

### 2.1 Barriers to Successful Clinical Trials and Drug Development in Acute Kidney Injury

***Patients and Comorbid Factors*** The rising incidence of AKI over the decades is associated with a changing spectrum of illnesses. In particular, there is evidence for a heavy burden of patients with significant comorbid and extrarenal complications [2, 5]. Supporting this, using the Deyo-Charlson comorbidity index, those patients with higher comorbidity were associated with a higher incidence of AKI especially if they were on mechanical ventilation [2]. In a multicenter study of 618 patients with AKI in the intensive care unit [PICARD (Program to Improve Care in Acute Renal Disease) network], the incidence of comorbid conditions was high, including 30% with chronic kidney disease, 37% with coronary artery disease, 29% with diabetes mellitus, and 21% with chronic liver disease [5]. AKI was accompanied by extrarenal organ system failure in most patients. These comorbid conditions are likely contributors to failed treatment regimens, especially if mortality is used as an endpoint for the clinical trial. Furthermore, drug development focused on isolated medical problems may fail due to the complex interplay of multiple comorbidities in a single patient.

***Pathogenesis of AKI Is Complex*** The pathogenesis of AKI is complex. Ischemia or toxins are major factors that precipitate injury, and, although the initiating events may be dissimilar, subsequent injury responses likely involve similar pathways. As an example, AKI associated with ischemia is due to a reduction of renal blood flow below the limits of blood flow autoregulation. A variety of molecular responses then occur that are "maladaptive" and stereotypical. These responses lead to endothelial and epithelial cell injury following the onset of reperfusion [6]. Pathogenetic factors, such as vasoconstriction, leukostasis, vascular congestion, apoptosis, and abnormalities, in immune modulators and growth factors have formed the basis of logical therapeutic interventions. However, many of these targeted therapies have failed, are inconclusive, or have yet to be performed [7, 8]. Given the complexity of the pathogenesis of AKI, it may be naïve to expect that one therapeutic intervention would have success unless that intervention focuses on prevention of AKI and targets a specific initiating etiology. This is true in that the greatest successes for therapeutic interventions have come in the prevention of contrast nephropathy: saline [9], sodium bicarbonate [10], low and isosmolar contrast [11, 12], and theophylline [13]. Given the multiple overlapping pathways involved in AKI, therapies may need to simultaneously target multiple pathways in order to achieve success [14]. However, the evolving and deepening understanding of the pathogenesis of AKI allows investigators to specifically target pathogenic pathways (e.g., the Toll-like receptors) that are logical and based upon sound reasoning.

***Acute Kidney Injury (AKI) Is a MultiSystem Disease*** While AKI is an independent risk factor for mortality from cardiopulmonary dysfunction [15], in most studies

of AKI, renal failure per se is usually not the cause of death [14]. In several studies, either congestive heart failure [16, 17] or noncardiogenic acute respiratory distress syndrome (ARDS) [18] is associated with AKI. Thus, the potential systemic effects of AKI involve multiple organs leading to high mortality. Animal studies have confirmed that isolated AKI may lead to distant cardiopulmonary dysfunction [18, 19]. Thus, the complexity created by the systemic effects of isolated AKI may contribute to ineffective treatments in the past. These observations also suggest that potential therapeutic strategies should not be limited to treatment of kidney injury alone but should be broad based to treat systemic effects of AKI.

### 2.2 Design Issues in Clinical Trials

Common design reasons for the inability to demonstrate that a particular therapeutic agent is beneficial include low statistical power, lack of a consensus definition of AKI in previous trials, improper endpoints, difficulty in timing administration of the drug, side effects of the drug, and patient heterogeneity [20]. Furthermore, difficulties in patient recruitment and randomization that controls for illness severity have also proven to be barriers to successful clinical trials. Three clinical trials in AKI serve as examples of these difficulties.

Recombinant human insulin-like growth factor I (rhIGF-I) reduced kidney injury when administered 30 min after reperfusion in experimental ischemia–reperfusion injury [21] In addition, rhIGF-I is known to decrease apoptosis and inflammation in experimental acute renal failure [22, 23]. Thus, it was surprising when, in human trials, rhIGF-1 failed to protect patients from the development of AKI. This may be, in part, due to hypotension associated with rhIGF-1 (42 vs. 27%), but in addition administration could have been delayed by as much as 6 days following diagnosis [24]. Because the therapeutic window for prevention of AKI is likely to be narrow, delayed treatment is likely to be unhelpful.

Similar design issues were seen in the trial of atrial natriuretic peptide (ANP). ANP is known to dilate afferent arterioles, constrict efferent arterioles, induce natriuresis, [25] and reduce ischemia–reperfusion injury in animal models. However, when infused into humans, anaritide (human atrial natriuretic peptide; 200 ng/kg/min) did not reduce 21-day dialysis-free survival [26]. A subgroup with oliguria seemed to fare better but was not confirmed in a subsequent study [27]. A confounding variable was the low blood pressure that occurred in the h-ANP group. In a subsequent study using a lower dose of h-ANP (50 ng/kg/min), significantly less hypotension was observed and 21-day dialysis survival and estimated glomerular filtration rate (GFR) were improved [28].

Lastly, dopamine has been shown to be ineffective in the treatment of human AKI [29–31] despite an increase in natriuresis. In animal studies it has been shown that, although dopamine increases outer medullary blood flow by 35%, it does not increase medullary $pO_2$, an important measure of tissue oxygen delivery during ischemia–reperfusion injury. Furthermore although dopamine reduced renal vascular resistance in patients without AKI, it paradoxically increased resistance in patients with AKI [32]. Thus, "low-dose" dopamine worsens renal perfusion in patients with AKI, which may in part explain the lack of success with this agent.

One of the greatest impediments to trial design is the fact that serum creatinine is a poor biomarker of AKI, yet it is commonly used to time interventions [4]. Many factors regulate the generation, volume of distribution, and excretion of creatinine. Net excretion of creatinine is due both to filtration and, to a variable degree, proximal tubule secretion. Thus, organic compounds and drugs may block creatinine secretion. Most importantly, the rise in serum creatinine is slow following AKI (Fig. 1). By the time a change is observed in serum creatinine, a critical therapeutic window may have been missed. The earliest evidence of injury precedes frank acute tubular necrosis and rises in serum creatinine and is likely the point at which interventions need to be introduced. Thus, the detection of the earliest evidence of AKI will ultimately necessitate the use of novel serum or urinary biomarkers. For example, patients with prerenal AKI could represent a group that demonstrates a graded increase in tubular enzymuria (biomarker) and other biomarkers that suggest the earliest evidence of epithelial cell injury yet insufficient

**Figure 1** Biomarkers for the early diagnosis of AKI are needed as increases in serum creatinine occur late in the course of the disease process.

to cause frank necrosis and demonstrable rises in serum creatinine. The use and validation of sensitive biomarkers may permit identification of individuals with early tubular injury and identify a subgroup of patients that might be the target for early intervention. Currently, several urinary biomarkers are being validated [33–37].

The majority of clinically significant AKI occurs in the intensive case unit (ICU). Nephrologists in this setting serve as consultants and typically care for patients only when significant rises in serum creatinine or oliguria develop. As stated above, at this point, significant injury has occurred and therapeutic interventions may be unsuccessful. Thus, to ensure success of any clinical trial, close collaboration between intensivists and nephrologists is required to identify appropriate patients at the earliest stages of injury. Unfortunately, this has not always occurred in the design and implementation of clinical trials.

Defining clinically significant AKI is critical. In the past, clinical trials have used widely varying definitions ranging from a 20–30% rise in serum creatinine to the need for dialysis, which has led to reported incidence of AKI of 1–25% [15, 38] and mortality rates varying from 28 to 90% [39, 40]. The absence of consensus on a definition for AKI led to the Acute Dialysis Quality Initiative (ADQI) and the development of the Acute Kidney Injury Network (AKIN), which represents the efforts of work groups that seek to develop consensus and evidence-based statements in the field of AKI. ADQI used a set of criteria called the RIFLE (Risk, Injury, Failure, Loss, and End stage) criteria [41] that has recently been modified by the AKIN working group. Validation of the classification and staging system of AKI will be required in future clinical studies and holds promise that this classification scheme can improve the design of trials.

Finally, appropriate endpoints for clinical trials in AKI need to be defined [42]. The endpoints can range from the need for dialysis at a specified time point to the development of renal recovery or mortality at a specified endpoint. These specific endpoint goals have important implications for the appropriate size and power of trials as well as the potential for finding a positive outcome. For instance, an intervention that may have a small effect on renal function would not be discovered in a trial that focused on total mortality and was powered for that outcome.

## 2.3 Drugs on the Horizon

Given the failure of multiple pharmaceutical agents in the therapy of AKI, novel agents are needed. A number of drugs and investigational compounds are currently undergoing evaluation for the treatment of AKI (Table 2).

### *Antiapoptosis/Necrosis Agents*

*Caspase Inhibitors* Caspases are a family of proteases involved in the initiation and execution phase of apoptosis. Nonselective and selective caspase inhibitors are effective in attenuating renal injury in ischemia- or endotoxemia-induced AKI when administered before or at the time of injury [23, 43, 44].

*Minocycline* Minocyclines are second-generation tetracycline antibiotics with proven human safety data. Minocycline is known to have antiapoptotic and anti-inflammatory effects. When administered 36 h before renal ischemia, minocycline reduced tubular cell apoptosis and decreased mitochondrial release of cytochrome c and p53 and upregulated bax [6]. Furthermore minocycline reduced kidney inflammation and also microvascular permeability [45, 46]. Currently, minocycline is undergoing testing in phase III clinical trials for renal protection.

*Guanosine and Pifithrin-a (p53 Inhibitor)* Guanosine triphosphate (GTP) salvage by exogenous administration of guanosine reduced renal tubular cell apoptosis, an effect associated with inhibition of p53 expression [47]. Pifithrin-α, a novel p53 inhibitor, also led to decreased tubule cell apoptosis and preserved renal function [48].

*Poly ADP-Ribose Polymerase (PARP) Inhibitor* PARP is a ubiquitous nuclear enzyme that participates in DNA (deoxyribonucleic acid) repair [49, 50]. Paradoxically, excessive activation of PARP from cellular injury leads to intracellular nicotinamide adenine dinucleotide $(NAD)^+$, and adenosine triphosphate (ATP) depletion, ultimately resulting in cell death. PARP overactivation has been known to play a role in the pathogenesis of ischemia–reperfusion injury to kidney, heart, and brain [51–53]. Inhibition of PARP immediately at reperfusion reduced injury. PARP inhibitors are currently in phase II clinical trials of reperfusion injury.

### *Free-Radical Scavengers*

*Deferoxamine* A key early feature of AKI is the generation of reactive oxygen species. The iron chelator deferoxamine is a well-known free-radical scavenger. In several models of AKI, deferoxamine has demonstrated a marked protective effect [54–57]. The protective effect of deferoxamine in different models suggests the central role of free radicals in acute renal failure. Studies in AKI are currently underway to test the efficacy of iron chelation.

### *Antisepsis*

*Ethyl Pyruvate* Pyruvate has been known as a potent endogenous antioxidant and free-radical scavenger, and its derivative, ethyl pyruvate, proved to be effective in reducing mortality in animal models of lethal hemorrhagic shock and systemic inflammation caused by endotoxemia or sepsis [58]. In addition to an effect on mortality, ethyl pyruvate also reduced kidney injury in a cecal ligation puncture (CLP) model of sepsis [59]. Ethyl pyruvate is a widely used food additive and has shown to be safe in phase I clinical trials. It is now being tested in a phase II trial in patients undergoing cardiopulmonary bypass (CBP).

*Activated Protein C* Activated protein C (APC) is a physiologic anticoagulant generated by the thrombin–thrombomodulin complex in endothelial cells. However, in addition to its effect on coagulation, APC has been shown to have anti-inflammatory, antiapoptotic effects [60, 61]. APC also attenuated renal ischemia reperfusion injury (IRI) by inhibiting leukocyte activation [62]. APC is currently approved by the Food and Drug Administration (FDA) in treating patients with an severe sepsis with an Acute Physiology and Chronic Health Evaluation (APACHE) score of 25 or higher.

*Insulin* Insulin resistance and hyperglycemia are common in critically ill patients and intensive insulin therapy targeting blood glucose level between 80–110 mg/dL reduced the incidence of ARF requiring dialysis or hemofiltration [63]. The relationship of hyperglycemia and adverse outcome in critically ill patients with AKI was recently also observed in subgroup analysis of Program to Improve Care in Acute Renal Failure (PICARD) study [64]. The mechanism for clinical benefit may relate the direct metabolic and nonmetabolic effects of hyperglycemia. Endothelial dysfunction and subsequent hypercoagulation, and dyslipidemia, commonly observed in critically ill patients can also be partially corrected by insulin independent of its blood glucose lowering effect [65, 66]. However, despite these promising results, the effect of intensive insulin treatment in the setting of AKI has not been tested and needs to be confirmed in appropriate powered randomized clinical trials.

### *Growth Factors*

*Recombinant Erythropoietin* Erythropoietin has been shown to have anti-inflammatory, antiapoptotic effects in ischemic brain damage, spinal cord injury, and retinal damage [67]. Exogenously admininistered erythropoietin before or at the time of reperfusion reduced kidney injury by reducing tubular necrosis and apoptosis [68–70]. It enhanced tubular proliferation in cisplatin-induced ARF [71] and also mediated mobilization and proliferation of endothelial progenitor cells (EPC) from the bone marrow that has been shown to participate tissue repair [72, 73]. Clinical trials of AKI using recombinant erythropoietin are currently in progress.

*Hepatocyte Growth Factor (HGF)* HGF can promote cell growth, motility, and morphogenesis of various types of cells [74, 75]. Renal expression of HGF and its receptor, c-met, increases after IRI, and exogenous administration of HGF reduces renal injury and accelerates renal regeneration in a murine model of AKI [76–78]. The mechanism of protection is thought to involve a decrease in leukocyte–endothelial interaction with reduced inflammation and also a decrease in tubular cell apoptosis [79]. Currently, phase I/II study of recombinant human HGF in fulminant hepatic failure patients and another phase II study of HGF via plasmid vector in critical limb ischemia patients with peripheral ischemic ulcer are underway. Experience in these clinical trials may shed light on human AKI.

### *Vasodilators*

*Carbon Monoxide Release Compounds and Bilirubin* Heme oxygenase (HO) induction plays a central role in limiting the extent of tissue injury [80, 81]. HO activity leads to the production of carbon monoxide (CO) and a potent antioxidant bilirubin, and it is thought that the protective effect of HO activation is through these factors. In renal IRI administration of CO donor compounds tricarbonyldichlororuthenium(II) dimer, ([Ru(CO)(3)Cl(2)](2), or tricarbonylchloro(glycinato) ruthenium(II) ([Ru(CO)(3)Cl(glycinate)] (CORM-3) 1 h before the onset of ischemia significantly decreased the levels of plasma creatinine 24 h after reperfusion as compared with vehicle-treated mice. This suggests that CO itself may be protective and limit renal damage in ischemia-induced ARF [82]. Bilirubin has also been shown to reduce kidney injury from IRI [83], and, when biliverdin and CO are used in combination, they are syngeristic in improving heart allograft survival [84].

*Endothelin Antagonist* A potent vasoconstrictor, endothelin-1 (ET-1) has been implicated to play important roles in animal models of AKI or radiocontrast nephropathy [85, 86]. ET-1 mediates its biological effects by binding to $ET_A$ or $ET_B$ receptors. In rat kidney, $ET_A$ receptor stimulation is known to mediate vasoconstriction, while $ET_B$ receptor activation can also mediate vasodilation by the generation of nitric oxide and prostacyclin [87, 88]. In addition, ET-1 can stimulate the expression of adhesion molecules and the production

cytokines from monocytes and neutrophils, suggesting the possible role of ET-1 in inflammation in AKI [89]. Several studies demonstrated the beneficial effect of selective $ET_A$ or nonselective endothelin receptor antagonist (ERA) in ischemic ARF, but the major limitation of those studies are the fact that ERA was administered before injury. Administration of the drug at a later time point during the reperfusion was ineffective. However, Wilhelm et al. recently showed that tezasartan, a dual ET1 receptor antagonist, attenuated renal injury even when administered after ischemia [90]. Currently, no clinical trial testing ERA in AKI is undergoing.

***Anti-inflammatory Drugs*** Inflammatory cells, including polymorphoneutrophil, monocytes, macrophages, and T cells, have received considerable attention as important contributors to ischemic acute renal failure. Several new compounds appear to be effective in reducing injury for ischemia–reperfusion through direct action on leukocytes.

*Spingosine 1 Phosphate (S1P) Analogs* S1P is a specific ligand for a family of G-protein-coupled endothelial differentiation gene (*Edg*) receptors (also referred to as S1PRs 1–5) that evoke diverse cellular signaling responses. S1PRs regulate different biological processes depending on their pattern of expression and the diverse G proteins present. S1P binds to receptors or acts as a second messenger to stimulate cell survival, inhibit cell apoptosis, and inhibit cell adhesion and movement [91]. An S1P analog, FTY720, acts as an agonist at four sphingosine 1 phosphate receptors, which lead to sequestration of lymphocytes in secondary lymphatic tissue [92]. In studies of ischemia–reperfusion kidney IRI, FTY720 or similar compounds produced lymphopenia and renal tissue protection [93–95].

*$A_{2A}$ Agonists and Other Adenosine Analogs* Adenosine binds to receptors that are members of the G-protein-coupled receptor family, which includes four subtypes: $A_1$-, $A_{2A}$-, $A_{2B}$-, and $A_3$-ARs (adenosine receptor subtypes) [96]. Accumulating data demonstrate that selective activation of $A_{2A}$-ARs reduces parenchymal injury in nonrenal tissue including heart, liver, spinal cord, lung, and brain [97–99]. The selective $A_{2A}$ agonist, ATL146e, is highly protective against ischemia–reperfusion (IR) injury of kidney and reduces injury by 70–80% [100, 101]. Following administration either before or immediately at the onset of reperfusion, ATL146e alone or in combination with a phosphodiesterase inhibitor reduced renal injury [102]. ATL146e is in human clinical studies for cardiac imaging, and current efforts are directed toward human clinical studies in AKI. Additional studies demonstrate that strategies using A1 agonists or A3 blockers may be effective in AKI [103, 104].

*Inducible Nitic Oxide Synthase Inhibitors* The role of nitric oxide and nitric oxide synthases has been extensively studied. Both in vivo and in vitro studies point toward the important role of inducible nitric oxide sythase (iNOS) in mediating injury to proximal tubules [105]. Selective iNOS inhibitors are currently used in human investigation.

FIBRATSE Peroxisome proliferator-activated receptors (PPARs) are transcription factors that regulate glucose, lipid metabolism. Recent studies have indicated PPARs play an important role in inflammation and immunity [106]. Pretreatment of animals with fibtrates (PPARa ligand) ameliorated cisplatin-induced renal dysfunction, and this was accompanied by suppression of nuclear factor (NF)-κB activation, cytokine/chemokine expression, and neutrophil infiltration, suggesting that the protective effect of fibrates are mediated through its anti-inflammatory effect [107].

*Other Compounds* Neutrophil gelatinase-associated lipocalin [108], interlewkin-6 (IL-6) and C5a antagonists [109]}, IL-10 [110], α-melanocyte-stimulating hormone [111] are other potential compounds that have multiple mechanisms of tissue protection and may be beneficial in human AKI.

***Conclusions*** Barriers to successful clinical trials have thwarted progress in developing effective therapeutics for AKI. Implementation of strategies to prevent or treat AKI will depend upon the coordinated efforts of academic institutions, private industry, and the federal government in developing and testing novel therapeutic agents in well-designed clinical trials.

Furthermore, the complexity of AKI is due in part to activation of multiple overlapping and distinct temporal pathways. Inflammation (cellular and humoral) is a key mediator of AKI. It is unlikely that targeting events that occur late in AKI or even a single pathway will be effective. It might be that new strategies to treat or prevent AKI will require compounds that target pathways more proximal to onset. Such strategies could include the use of compounds that affect multiple pathways or combination therapy that targets several areas, rather than one.

## 3 DRUG DEVELOPMENT FOR POLYCYSTIC KIDNEY DISEASE

Autosomal-dominant polycystic kidney disease (ADPKD) is typified by the progressive development

**Figure 2** Gross appearance of kidneys from a patient with autosomal-dominant polycystic kidney disease.

**TABLE 3 Potential Experimental Targets for Drug Development in ADPKD**

| Target System | Potential Drugs |
|---|---|
| Renin–angiotensin system[a] | ACE inhibitors, angiotension receptor blockers |
| Vasopressin[a] | V2-receptor antagonists |
| Endothelin | Bosentan, darusentan |
| mTOR[a] | Sirolimus, temsirolimus, everolimus |
| Caspase system | IDN-8050 (pan-caspase inhibitor) |
| Somatostatin[a] | Octreotide |
| Epidermal growth factor receptor | EKI-785, pelitinib |

of bilateral kidney cysts (Fig. 2) that ultimately lead to deterioration of kidney function and the need for renal replacement therapy (dialysis or transplantation) in 50% of affected individuals by the fifth decade of life. It is the most common life-threatening hereditary disease. ADPKD has an estimated prevalence of between 1 in 400 and 1 in 1000 [112]. In the United States, approximately 2144 patients every year start renal replacement therapy due to ADPKD [113], with an annual incidence rate of end-stage renal disease in men and women of 8.7 and 6.9 per million, respectively [113]. The higher incidence in men suggests a more progressive disease in this population.

ADPKD is a genetically heterogeneous disorder with two genes identified: *PKD1* (chromosome region 16p13.3, accounting for around 85% of cases) and *PKD2* (chromosome region 4q21, around 15% of cases) [114, 115]. Polycystin (PC)-1 encoded by *PKD1* has a large extracellular region, 7–11 transmembrane domains and a C-terminal cytoplasmic tail [114]. Based upon its structure and homology to other proteins, it has been suggested that PC-1 may play a role in cell–cell or cell–matrix interactions [116]. It is believed that PC-1 is a receptor for an unidentified ligand and may function as a mechanoreceptor. PC-1 is localized to the primary cilium, a single hairlike organelle projecting from the surface of most mammalian cells [116]. The protein has also been localized to tight junctions, adherens junctions, desmosomes, focal adhesions, and apical vesicles [117]. The C-terminal tail of PC-1 contains tyrosine and serine sites that can be specifically phosphorylated by c-Src, focal adhesion kinase, protein kinase A, and protein kinase X as well as heterotrimeric G-protein activation [118]. PC-1 may also be involved in intracellular signaling resulting in modulation of gene transcription [118].

Polycystin (PC)-2 is encoded by *PKD2* and contains an N-terminal cytoplasmic region, six transmembrane domains, and a C-terminal cytoplasmic tail [119]. The transmembrane domain has homology to PC-1 and transient receptor potential (TRP) channel subunits [119]. This domain acts as a calcium-permeable cation channel [120]. Studies have demonstrated that PC-1 and PC-2 interact to form a functional complex that acts as a mechanoreceptor on cilia to detect changes in flow [121]. These changes lead to calcium influx through the PC-2 channel, which is further amplified by intracellular calcium release [121]. Furthermore, these rises in intracellular calcium limit cyclic adenosine monophosphate (cAMP) accumulation [122]. Overall, these complexes are essential for maintenance of the differentiated, polarized, predominantly reabsorptive phenotype in tubular epithelial cells, which normally have low rates of proliferation and apoptosis [118]. Mutations in either PC-1 or PC-2 lead to polarization defects, cellular differentiation, proliferation, development of a secretory (rather than resorptive) phenotype, and a high rate of apoptosis that culminate in the development of renal cysts and progressive kidney failure.

The genetic and molecular biological advances in the understanding of the pathogenesis of ADPKD have led to the identification of several key pathways for drug development (Table 3). These strategies are now entering clinical trials to determine possible efficacy in slowing or halting the progression of ADPKD.

### 3.1 Barriers to Successful Clinical Trials in ADPKD

One of the greatest barriers to designing a clinical trial that would test the efficacy of a therapeutic agent in slowing or halting the progression of kidney disease in

ADPKD is that the natural history of progression occurs over many decades. This makes any trial not feasible if the endpoint is change in renal function over time. This same argument holds for many of the progressive renal diseases that slowly lead to deterioration of renal function. To circumvent this critical problem, robust surrogate markers are required that allow for the determination of changes on a shorter time scale but are highly correlated with long-term outcomes. For ADPKD, recent studies have determined that both baseline kidney volume and changes in kidney volume that occur over relatively short time periods (1–5 years) highly correlate with long-term changes in GFR [123]. Thus, higher rates of kidney volume increase are associated with progressive decline in GFR, and this surrogate marker can be used for design and implementation of clinical trials.

### 3.2 Molecular Targets for Therapeutic Drugs in ADPKD

***Vasopressin Receptor Antagonists*** As mentioned above, calcium homeostasis is abnormal in ADPKD. This may lead to increased renal concentrations of cAMP by stimulation of $Ca^{2+}$-inhibitable adenylyl cyclase 6 or inhibition of $Ca^{2+}$-dependent phosphodiesterase 1 [124]. cAMP stimulates mitogen-activated protein kinase (MAPK) and extracellularly regulated kinase (ERK) signaling and cell proliferation in renal epithelial cells of patients with ADPKD, whereas it has an inhibitory effect in wild-type cells [125]. The abnormal proliferative response to cAMP is directly linked to alterations in intracellular $Ca^{2+}$ concentration since it can be reproduced in wild-type cells by lowering the intracellular concentration of $Ca^{2+}$ [126]. Furthermore, the increases in intracellular cAMP may be related to both upregulation of the vasopressin V2 receptor (VPV2R) and high circulating vasopressin concentrations [127].

On the basis of the observed VPV2R activation of adenylyl cyclase and cAMP in cysts from cells from renal cysts, recent studies examining the effect of a nonpeptide vasopressin receptor antagonist (OPC-31260) have been conducted in several murine and rat models of PKD (Fig. 3). The drug prevented renal cAMP accumulation, inhibited renal cystogenesis and increase in renal cyst size, and decreased blood urea nitrogen levels [128]. Administration of the drug, even after the cystic disease was already established, halted the progression or caused regression of the renal cysts [128, 129]. The decrease in cAMP is associated with inhibition of Ras and ERK activity [130].

**Figure 3** Effects of the vasopressin receptor antagonist OPC-31269 on kidney weight, cyst volume, and blood urea nitrogen (BUN) in a murine model of ADPKD. (Adapted from ref. 127.)

Several VPV2R antagonists are currently in phase III clinical testing for the therapy of hyponatremia in patients with the syndrome of inappropriate antidiuretic hormone secretion and for patients with disorders of water retention such as congestive heart failure (Table 4). These drugs are attractive since they are relatively selective for the renal VPV2R and side effects have mostly included moderate thirst that is well tolerated.

An antagonist with high potency and selectivity for the human VPV2R, tolvaptan, has completed phase II testing in patients with ADPKD and a phase III clinical trial is now well underway.

***Somatostatin Antagonists*** As discussed above, cyst proliferation and fluid secretion into the cysts is under the control of cAMP. There are five receptors for somatostatin that bind to somatostatin or somatostatin analogs with various affinities [131]. The somatostatin type 2 receptor has been detected in the kidney and its stimulation results in inhibition of cAMP and stimulatory action on phosphatase and phospholipase C [132]. Mechanistically, this would seem an ideal target for therapy. Supporting this was the finding of the inhibition

of cyst growth in an ADPKD patient with a pituitary adenoma treated with octreotide (a somastatin analog) for 2 years [133].

Recently, a randomized, cross-over, placebo-controlled trial has been conducted to evaluate the benefits and adverse effects of 6 months' treatment with slow-release octreotide or placebo in patients with ADPKD [133]. In the group of patients receiving octreotide, there was a 60% reduction in cyst volume, whereas there was no change in the placebo group. There was no change in GFR noticed in the octreotide group. These encouraging findings will need to be verified in larger and longer trials.

***Mammalian Target of Rapamycin (mTOR)*** Polycystin 1 has been demonstrated to interact with the tuberous sclerosis gene product tuberin [134]. There is a convergence of signaling pathway activation downstream of these proteins that leads to activation of the target of rapamycin (mTOR) [135]. mTOR is a serine threonine kinase that plays an important role in protein translation, cell growth, and proliferation [136]. Consistent with this finding, patients with ADPKD have shown increased mTOR activity [137].

On the basis of the hypothesis that mTOR in renal cystic cells leads to abnormal cyst formation, several studies have been conducted to evaluate the effects of mTOR inhibitors. Sirolimus and everolimus are FDA-approved specific inbitors of mTOR [138]. These drugs reduce cell growth, the rate of cell proliferation, and the rate of cell cycle progression [138]. In an rat model of PKD, sirolimus decreased tubular cell proliferation and inhibited cyst formation and renal enlargement [139]. Most recently, a retrospective study of ADPKD patients who had received a kidney transplant demonstrated that sirolimus treatment (as part of the immunosuppressant regimen) significantly decreased renal volumes of the cystic kidneys [140]. Phase III clinical trials of mTOR inhibitors are now underway to test this hypothesis in a prospective manner.

***Epidermal Growth Factor Receptor*** There are numerous studies that support a strong role of the epidermal growth factor (EGF)/transforming growth factor (TGF)–α/EGF receptor axis in promoting tubular epithelial cell proliferation, and cyst formation and enlargement [141]. Furthermore, studies have shown that renal cyst fluid from patients with ADPKD, as well as animal models of PKD, contain EGF-related peptides, and there is overexpression of the EGF receptor [142]. These receptors have a high affinity for these cyst-derived EGF-related peptides and result in autoactivation (through tyrosine kinase activity) of signaling cascades resulting in increased cellular proliferation [143].

Inhibition of EGF receptor tyrosine kinase activity significantly inhibits cyst development in animal models of PKD, suggesting that this may be a viable therapeutic option [144, 145]. Several selective therapeutic inhibitors with limited adverse reaction are in phase I or II clinical trials.

### 3.3 Conclusions

The rapid breakthroughs in the molecular understanding of pathogenesis of ADPKD had made several biochemical pathways logical avenues for potential therapeutic agents (Table 3). These therapeutics share a common theme: namely, intervening on growth promoting pathways to halt cyst formation and growth. Several

clinical trials are now ongoing, and it is hoped that a potential therapy for a disease that up until now has had no effective therapy will be available soon.

## 4 THERAPEUTIC AGENTS TO SLOW THE PROGRESSION OF CHRONIC KIDNEY DISEASE

Chronic kidney disease is growing in epidemic proportions. Within the United States both the incidence and prevalence of CKD are climbing annually. Estimates project that by 2014, 800,000 individuals will require either dialysis treatment or transplantation for CKD, a 60% increase from 2001. From 1991 to 2000 the prevalence of patients requiring some form of therapy for CKD within the U.S. population increased by 97% and the incidence by 57% [146, 147]. Obviously, this makes this area a rich opportunity for the development of novel therapeutic agents to both halt the progression of CKD to end-stage renal disease as well as treat the complications associated with the loss of kidney function.

### 4.1 Natural History of Progressive Chronic Renal Disease

The nephron is the fundamental structural and filtration unit of the kidney. The human kidney is composed of approximately 1–1.5 million nephrons. Each nephron is composed of multiple parts that provide for filtration of the blood and processing of the filtrate via resorption and excretion of both water and solute to create urine, which is excreted from the body. Chronic kidney disease progresses via a vicious cycle of nephron damage followed by an adaptive response that in many circumstances is critical in leading to CKD [148]. After an initial insult to the kidney (such as that due to hypertension, diabetes mellitus, or immune-complex-mediated glomerular disease of lupus nephritis), the kidney responds via a process called adaptive hyperfiltration in which the glomerular filtration rate (the volume of fluid filtered from the glomerular capillaries into Bowman's capsule per unit time) of the remaining normal nephrons is increased. The increased filtration rate of the surviving nephrons allows the remnant nephrons to do the filtration work previously performed by the entire kidney, allowing the serum creatinine in mild or early kidney disease to remain at or near the normal range. Adaptation within the tubules of surviving nephrons allows serum electrolytes to be maintained as well [149].

Although initially protective, adaptive hyperfiltration results in progressive damage to the surviving nephrons via elevated intraglomerular pressure and cellular damage. This resulting nephron damage due to hyperfiltration induces further adaptive hyperfiltration in a viscous cycle that contributes to the progression of kidney disease. The combination of this adaptive cycle, continuation/worsening of the initial disease insult, and multiple other pathophysiologic factors contribute to the chronic and often devastating progression of CKD.

### 4.2 Obstacles to the Development of Novel Therapeutic Agents to Prevent Progression of CKD

Just as with ADPKD, the time course for the progression of most kidney diseases occurs over a time span of decades. Thus, novel biomarkers that predict the risk of progression must be identified as surrogate markers for CKD progression. The biomarker most often studied is urine microalbumin or urine protein. Multiple studies have demonstrated that the level of urine protein correlates with the risk for progression and that treatment strategies that lower proteinuria lead to renal protection [147]. However, other biomarkers are needed, and their robustness in predicting CKD must be so great that the FDA would approve them as surrogate outcome markers for worsening renal function in clinical trials. Thus far, no such biomarkers exist.

### 4.3 Treatment Strategies

Treatment strategies for CKD can be multifaceted. There are wider population goals, which include improving initial identification of CKD patients so as to begin treatment earlier (with the hope that earlier therapy will prevent later progression). There are also cause-specific strategies that rely on appropriate and early therapy of underlying etiologies. For example, these would include aggressive glycemic control for diabetics, and immunosuppression for inflammatory diseases such as systemic lupus erythematosis. However, some responses of the kidney to injury are relatively stereotyped and allow for the development of more global preventative strategies that can be applied across the spectrum of causes [150]. Some of those will be discussed here and are listed in Table 5. In general, strategies to protect the kidney have thus far focused on agents that lower blood pressure as well as lower urine protein excretion.

***Angiotensin-Converting Enzyme Inhibitors (ACEi)*** The rennin–angiotensin–aldosterone system (RAAS) is activated by multiple stimuli. The kidneys respond to hypotension, decreased sodium concentration in the distal tubule, and decreased blood volume by releasing renin from the juxtaglomerular apparatus (Fig. 4). Renin, a proteolytic enzyme, cleaves angiotensinogen

(produced in the liver and released into the circulation) into angiotensin I. The angiotensin-converting-enzyme (ACE) present mainly in the pulmonary capillaries cleaves angiotensin I into angiotensin II. Angiotensin II has effects on many organs, but, most importantly, it acts as a potent vasoconstrictor and leads to the release of aldosterone from the adrenal gland. As shown in Figure 4 there are several potential steps in the pathway that can be blocked, and therapeutic drug development has focused on these various steps.

In the kidney, angiotensin II stimulates smooth muscle contraction; and, specifically at the glomerular level, angiotensin II causes asymmetric constriction of the efferent >> afferent arterioles of the glomerular apparatus. The increased efferent arteriole pressure results in increased hydrostatic pressure in the glomerular capillaries and increased GFR (responsible for the hyperfiltration phase of kidney injury). This effect of the RAAS has made the system a target to break the cycle of adaptive hyperfiltration that characterizes the progression of chronic kidney disease.

**TABLE 5 Therapeutic Strategies for the Treatment of Chronic Kidney Disease**

1. Optimal blood pressure control to <125/75 mmHg
   a. Utilization of drugs that preferentially block the renin–angiotensin system
      i. ACE inhibitors
      ii. Angiotensin receptor blockers
      iii. Direct renin inhibitors
      iv. Combination therapy
2. Use of statin agents
3. Use of drugs to limit oxidative damage
4. Nutritional management
5. Anti-inflammatory drugs
6. Treatment of specific etiologies
   a. Diabetes mellitus
   b. Systemic lupus eryuthematosis
   c. Other inflammatory diseases

Initial work upon a component of the venom of the *Bothrops jararaca* pit viper led to the discovery of a peptidic fraction referred to as bradykinin potentiating factor (BPF) that potentiated the effects of bradykinin in animal models by inhibition of bradykinin breakdown in the lung [151–154]. Further work demonstrated that BPF also inhibited the conversion of angiotensin I to angiotensin II. The component that was subsequently isolated was a nonapeptide, teprotide, which had the greatest ACE inhibition potency both in vitro and in vivo [151–156].

Subsequently, synthetic compounds were produced mimicking the structure of teprotide that were capable of ACE inhibiton and blood pressure lowering, utlimately leading to the discovery of captopril, the first orally bioavailable ACEi [151]. Furthermore, this discovery was one of the first examples of specific structurally defined pharmaceutical development.

Early animal experimentation evaluated the efficacy of ACEi as a means of slowing the progression of CKD [156]. Much of this experimentation utilized a model system whereby the animals underwent a four-fifths nephrectomy to lead to significant renal mass reduction.

**Figure 4** Renin–angiotensin system. Renin released by the kidney acts as a proteolytic enzyme to cleave angiotensinogen to angiotensin I, which is cleaved to the biologically active angiotensin II. Angiotensin II can bind to either the type 1 or 2 angiotensin receptor to achieve their biological effects. Drugs that act on the renin–angiotensin system include: (1) direct renin inhibitors, which block the renin-mediated conversion of angiotensinogen to angiotensin I; (2) ACEi, which block the conversion of angiotensin I to angiotensin II; and (3) angiotensin receptor blockers, which block the AT1 receptor.

This leads to a marked increase in both perfusion and filtration of the remaining nephrons. These changes result in development of progressive proteinuria and eventual glomerulosclerosis, thus serving as a model of progressive kidney disease [156].

Importantly, ACEi protected these experimental rats from CKD progression. In these animal models, ACEi resulted in reduced capillary pressure within the glomerulus, inhibition of renal cellular growth, and reduced permeability of the glomerular capillary to protein, which reduced proteinuria and prevented the development of glomerulosclerosis [156]. Other animal research demonstrated that rennin–angiotensin system blockade exerts potent antiatherosclerotic effects, which are mediated by their antihypertensive, anti-inflammatory, antiproliferative, and oxidative stress-lowering properties [157].

Based upon these encouraging preclinical studies, many large clinical trials have been performed demonstrating the effectiveness of ACE inhibition in a CKD preventative strategy. In an early trial, patients were randomized to treatment with captopril or nifedipine for 3 years [158]. CKD progression was measured every 2 months. A greater decrease in urine protein excretion was demonstrated in ACEi-treated patients and in those patients with a mean blood pressure (BP) < 100 mmHg, a significantly slower decrease in GFR was demonstrated in patients treated with ACEi [158]. The seminal trial supporting the use of ACEi in a renal protective strategy occurred in 1993, when is was shown that captopril when given to type I diabetes with significant diabetic nephropathy led to a dramatic decrease in the rate of progressive renal disease (Fig. 5) [159]. Several other important studies have confirmed the significant benefits of ACEi (independent of blood pressure lowering) in patients with CKD across diverse causes [160, 161]. Overall, in a meta-analysis that compared blood pressure regimens containing an ACEi with regimens not including ACEi the risk of either doubling serum creatinine or reaching end-stage renal disease was reduced by 36% in ACEi-treated patients [162]. Furthermore, a reduction in urine protein excretion occurred only in patients treated with ACEi [162].

**Figure 5** Effects of the ACEi captopril on the progression of CKD in type I diabetics with existing nephropathy. (Adapted from ref. 158.)

As described above, targeting and inhibiting the angiotensin-converting enzyme also potentiates the effects of bradykinin via inhibition of bradykinin-destroying enzymes in the lung. Potentiation of bradykinin activity leads to two of the most frequently cited side effects of ACE inhibitors. The first is angioedema. Bradykinin is a potent vasodilator. Vasodilation can lead to rapid accumulation of interstitial fluid and swelling. When this swelling occurs around the mouth or the mucosa of the mouth or throat, stridor and respiratory compromise can quickly occur. Angioedema of differing severities and locations can occur in 0.1–0.2% of ACEi-treated patients and can be life threatening. ACE inhibitors can also result in a chronic cough thought to occur as a result of sensitization of airway sensory nerves by potentiated bradykinin [162]. Although less life threatening than angioedema, the cough can result in decreased patient comfort and quality of life and resulting decrease in medication compliance. The chronic, usually dry and nonproductive cough can occur in up to 20% of patients taking ACEi [163].

***Angiotensin Receptor Blockers*** Alternative methods of RAAS blockade have been developed. The angiotensin II type 1 receptor (AT1) receptor is thought to be the mediator of nearly all of the deleterious effects of angiotensin II signaling [164]. Through AT1 signaling, angiotensin II induces vasoconstriction, decreased renal blood flow, vascular smooth muscle cell growth, and proliferation, cardiac left ventricular hypertrophy, and sympathetic nervous system activation [164]. Agents that target the AT1 receptor (angiotensin receptor blockers, or ARBs) were, therefore, developed to attack the RAAS without targeting the ACE [164]. These agents should be devoid of the side effects described above for ACEi. Currently, seven branded ARBs are available in the United States.

Blockade of the AT1 receptor is often discussed as physiologically providing more complete termination of the negative signals of the RAAS compared to ACE inhibitors [165]. This is due to the fact that enzymes other than ACE, including trypsin, cathepsin G, chymostatin-sensitive angiotensin II generating enzyme (or CAGE), and chymase, all catalyze the formation of angiotensin II from angiotensin I [165]. Therefore, ARBs could theoretically achieve a higher degree of RAAS blockade.

Furthermore, by avoiding inhibition of ACE, AT1 receptor antagonists do not potentiate bradykinin. This

avoids triggering the mechanism of the chronic cough and angioedema seen with ACEi.

Finally, by blocking the AT1 receptor, increased levels of angiotensin II are potentially available to activate the angiotensin type 2, or AT2, receptor (Fig. 4). At the AT2 receptor, angiotensin II signals largely favorable effects, regulating differentiation and proliferation of cells, controlling tissue regeneration and apoptosis, as well as vasodilatation [162, 165]. Thus, ARBs have several potential advantages over ACEi: (1) better side effect profile, (2) more complete RAAS blockade, and (3) stimulation of the AT2 receptor.

The AT1 antagonists have now been well studied in clinical trials and demonstrated clearly to prevent the progression of CKD (diabetic or nondiabetic). For example, in the Irbesartan Diabetic Nephropathy Trial (IDNT), patients with diabetes mellitus type II (DMII) were randomized to daily irbesartan, amlodipine or placebo [166]. The primary combined endpoint was doubling the baseline serum creatinine, development of end-stage renal disease (ESRD), or death. While amlodopine demonstrated no benefit, the irbesartan group had a 20–23% lower incidence of achieving the primary endpoints. This suggests that in patients with type II diabetes, irbesartan helps to halt CKD progression beyond its blood pressure effect. [167]. Similar results have been seen in other trials of ARB [168, 169].

***Direct Renin Inhibitors*** In viewing the RAAS pathway, a logical step for blockade is at the level of renin. Blockade of this critical initial step would allow downregulation of the entire RAAS, including allowing the production of substrates for alternative non-RAAS pathways. However, the development of an orally active, bioavailable compound was difficult. In 1995, alliskiren was patented and was the first viable direct renin inhibitor. The drug is similar in structure to renin's natural substrate, angiotensinogen, but is a nonpeptide [170]. However, since renin is a species-specific enzyme, further preclinical testing required the development of a novel transgenic rat model outfitted with the human renin and angiotensinogen genes that allowed the testing of aliskiren in an animal model [170]. Preclinical data demonstrated that aliskiren prolonged survival, decreased cardiac hypertrophy, and the inducibility of arrhythmias, proteinuria, and attenuated inflammation in this model [170]. All these features might result in improved target-organ damage. Studies in humans attest to an effective BP-lowering action, a largely side-effect-free profile, and the option of several combination therapies [171]. Furthermore, recent data has now demonstrated significant falls in urine protein excretion in patients with nephropathy who receive a combination of aliskiren and losartan [172]. Aliskiren is the first of a novel antihypertensive drug class.

From a drug development strategy the RAAS pathway has provided a logical and rich source of targets. Thus far, all agents that effectively downregulate this system (acting at several different sites) have demonstrated clinical benefit. The next step in development will be clinical trials to test these various agents in combinations to more fully suppress the RAAS in the hope of better organ protection.

***Statins*** Multiple large clinical trials have shown statins to be the most effective pharmaceutical means of lowering low-density lipoprotein (LDL) cholesterol values and of significant value in preventing both primary and secondary cardiovascular outcomes. Cardiovascular events are one of the main causes of mortality and morbidity in patients with CKD [173]. Perhaps the best quantitation of this relationship is from analysis of the National Health and Nutrition Examination Survey population [174]. This work demonstrated increased cardiovascular disease mortality in patients with both reduced GFR and increased proteinuria. Mortality rates related to cardiovascular disease in this population were 4.1, 8.6, and 20.5 deaths/1000 person-years among participants with an estimated GFR of ≥90, 70–89, and <70 mL/min, respectively.

Implementation of statin therapy in CKD patients would thus be logical to treat a major cause of mortality in this population. However, there are also other means by which statin therapy could theoretically be beneficial in slowing the progression of CKD. Statin therapy is highly anti-inflammatory and markers of inflammation such as C-reactive protein fall significantly once statins are initiated, and this effect is independent of its effect on cholesterol levels [175]. By decreasing serum levels of inflammatory cytokines, it is possible that statins could benefically impact one of the pathways of CKD progression [176].

A second mechanism by which statin therapy could potentially be useful in treatment of the progression of chronic kidney disease is via the effects these drugs have on the vasculature. Statin therapy has been proven to have beneficial effects on both endothelial function as well as vascular tone [177–179]. Theoretically, these improvements in vascular function could lead to improved renal blood flow and function. Interestingly, statin use for organ protection outside of the cardiovascular system has also been proposed for the central nervous system [180].

In terms of clinical outcomes, a post hoc analysis of the Heart Protection Study demonstrated that progressive creatinine elevation was slowed in the simvastatin-treated group [181]. Pravastatin in the Cholesterol and

Recurrent Events (CARE) trial demonstrated an overall reduction in the rate of CKD progression in patients treated with pravastatin of 34% [182]. This equates to an absolute reduction in the rate of GFR decrease by 0.2 mL/min per year in patients treated with pravastatin versus placebo. These encouraging results require validation in long-term, large multicenter clinical trials.

### 4.4 Drugs Specifically Targeted for Diabetic Kidney Disease

Diabetic nephropathy is the most common cause of ESRD in the United States and represents 44 of all new cases of ESRD in the United States. Diabetic nephropathy is distinct from other forms of CKD in that it is characterized by particular pathological abnormalities such as glomerular basement membranes (GBM) thickening and mesangial expansion that alters the configuration of the normal glomerulus structure [183].

The primary goals toward treatment of diabetic nephropathy are strict blood sugar and blood pressure control as well as treatment with ACEi, ARBs, and statins (as described above). In addition to these treatment goals, other new modalities are being developed to specifically target the glomerular abnormalities of diabetic nephropathy. This effort is driven by an extensive knowledge of the pathogenesis of diabetic nephropathy (Fig. 6).

**Figure 6** Pathogenetic pathways for diabetic nephropathy. Under the influence of hyperglycemia, free fatty acids, and insulin deficiency or excess, there is progressive activation of growth factors, cytokines, and the tissue renin–angiotensin system (RAS). This ultimately leads to damage to cellular membranes, activation of plasminogen activator inhibitor (PAI), and decreases in plasminogen activator (PA) and the pathological hallmarks of diabetic nephropathy (matrix expansion and glomerular basement membrane thickening).

***Sulodexide*** This agent is comprised of four linked glycosaminoglycan (GAG) polysaccharides that are isolated from porcine intestinal mucosa [184]. Although the exact mechanism of GAGs in diabetic nephropathy patients is unknown, preclinical studies and functional theory suggest that these compounds can prevent or reverse GBM thickening, prevent and correct GBM anionic charge depletion via both direct deposition as well as induction of heparin sulfate synthesis and sulfation, as well as inhibit heparinase-1 activity [185]. In preclinical work, sulodexide also suppressed early pathological mesangial cell proliferation [186]. The clinical development of sulodexide, which has occurred over the past decade, has included eight small exploratory European trials, a phase II European dose-ranging study, and a phase III trial initiated in the United States in 2004. No serious adverse events have been noted [187]. Encouragingly, there have been significant reductions in urine protein excretion in those patients receiving sulodexide [188]. However, definitive results will require the completion of the U.S. study.

***Pyridoxamine*** This agent is an effective inhibitor of the formation of advanced glycation end products (AGEs) that arise from the breakdown of glycated proteins (Amadori products) [189]. AGEs are thought to be intimately involved in the pathogenesis of diabetic complications [189]. Pyridoxamine is a derivative of vitamin $B_6$, and several studies have now demonstrated that oral pyridoxamine is highly effective in maintaining glomerular function in diabetic animal models [190]. The drug has shown a favorable safety profile in phase II testing [191]. In a single study, the rate of increase in serum creatinine in the pyridoxamine group tended to be lower compared with placebo [191]. Further studies are ongoing.

***Ruboxistaurin*** Protein kinase C (PKC) is a group of multifunctional isoenzymes involved in signal transduction that leads to cell growth, fibrosis, and tissue injury [192]. PKC activity is increased in diabetics, and it is believed that inhibition of PKC activity could be beneficial in preventing both micro- and macrovascular complications of diabetes [193]. Ruboxistaurin is a specific inhibitor of the PKC-β isoform [194]. It has been extensively evaluated in animal models and shown to normalize glomerular hyperfiltration (an early sign of diabetic nephropathy) and attenuate proteinuria [195]. In a pilot trial, 123 patients with diabetic nephropathy were randomized to placebo or ruboxistaurin. Ruboxistaurin led to significant reductions in proteinuria and maintained renal function over one year [196]. The drug has been more extensively studied for the prevention of retinopathy and is now under FDA review for this indication

[197]. Larger scale trials investigating renal protection are underway.

## 5 TREATING THE COMPLICATIONS OF CKD: VITAMIN D ANALOGS

One of the most common complications of advanced CKD is the development of metabolic bone disease due in part to a combination of a deficiency of active vitamin D as well as impairments in renal phosphorus excretion. The precursor of active vitamin D can be acquired from the diet from plant sources in the form of vitamin $D_2$ or from animal sources as the fat-soluble steroid vitamin $D_3$ (cholecalciferol). If not acquired in the diet, vitamin $D_3$ can be synthesized in the human skin where ultraviolet radiation results in cleavage of 7-dehydrocholesterol and formation of vitamin $D_3$. In the microsomes and mitochondria of the liver, hydroxylation by cytochrome-P450-like enzymes results in formation of 25-hydroxycholecalciferol or calcifediol. This is then transferred to the proximal tubule cells of the kidney where a second hydroxylation is performed by 25(OH)D-1-α-hydroxylase to create the mature hormone 1,25-dihydroxyvitamin D or calcitriol [198, 199] (Fig. 7).

Calcitriol alters gene expression by binding with high affinity to its intracellular receptor, the vitamin D receptor (VDR), which acts as a nuclear transcription factor. Liganded VDR undergoes conformational change and forms a heterodimer with a second protein, the retinoid X receptor (RXR). This, in turn, binds to DNA elements in the promoter regions of target genes described as vitamin D response elements (VDREs). Binding to the VDREs may promote transcription, as is the case with osteocalcin in the osteoblast, or inhibit transcription, as for the parathyroid hormone (PTH) in the parathyroids, by either enhancing or repressing the activity of transcription machinery [198, 200].

The development of advanced CKD (usually when the GFR is less than 60 mL/min) results in progressive loss of nephron mass, including the loss of proximal tubule cells capable of producing mature, active vitamin D, and thus vitamin D deficiency ensues [198]. Deficiency of mature vitamin D promotes the hyperplasia of parathyroid gland tissue and increased synthesis of PTH. Vitamin D deficiency also decreases serum calcium levels via decreasing gut absorption of calcium. The resulting serum hypocalcemia triggers further increased secretion of PTH. Thus, the deficiency of vitamin D leads to a characteristic biochemical abnormality seen in patients with CKD: secondary hyperparathyroidism. The consequences of secondary hyperparathyroidism include: (1) enhanced bone resorption triggered by elevated PTH levels (osteitis fibrosa cystica) leading to spontaneous fractures and (2) in the setting of an elevated calcium–phosphate product (approximately 30 $mg^2/dL^2$ in normal patients and up to 60–70 $mg^2/dL^2$ in patients with advanced CKD) metastatic calcifications develop in arteries, soft tissues, and organs with effects ranging from ischemia to organ failure [201, 202].

**Figure 7** Biosynthetic pathway for active vitamin D production.

Given that vitamin D deficiency is a primary cause of these abnormalities in CKD patients and that 1-α-hydroxylation is impaired in CKD, vitamin D analogs not requiring hydroxylation in the kidney have been developed to treat this condition. These include calcitriol, doxercalciferol, and paricalcitol in the United States [203].

### 5.1 Multiple Vitamin D Analogs

The major goal of the treatment of the vitamin D deficiency associated with CKD is to achieve suppression of PTH secretion, while limiting the actions of vitamin D on intestinal calcium and phosphorus absorption. To achieve this, drug development has utilized the variable affinity of vitamin D receptors in different tissues to develop an analog that can signal the parathyroid tissues to inhibit their hyperactivity and yet avoid the intestinal effects that would drive up the serum calcium–phosphorus product and lead to an increased risk for metastasic calcification. The efficacy of these medications have been individually studied in CKD patients [203].

Calcitriol is the natural form of active vitamin D and is available in an oral and intravenous form. It was the first agent administered to treat the metabolic bone disease of CKD and is the basic preparation to which others are compared for efficacy and safety profiles.

Paricalcitol (19-nor-1-α,25-dihydroxyvitamin $D_2$) is the classic "second-generation" vitamin D analog. Initial analysis of paricalcitol suggested that this medication was as efficacious as calcitriol with regards to lowering serum PTH levels [203]. It also suggested that the paricalcitol was less likely to result in hypercalcemia and that, therefore, the medication likely had a wider therapeutic window to suppress PTH without the hypercalcemia and hyperphosphatemic effects [204, 205]. The mechanism that explains this selectivity is not understood. Paricalcitol and calcitriol have been compared to each other in clinical trials. In a seminal study, paricalcitol was compared with calcitriol in 263 hemodialysis patients with plasma PTH levels greater than 300 pg/mL and a serum calcium phosphate product less than 75 $mg^2/dL^2$ [206]. Primary endpoints of this study included the ability of each drug to reduce the plasma PTH to 50% of baseline values; the incidence of hypercalcemia and/or a single occurrence of an elevated calcium–phosphorus product. In this study, no statistically significant difference was found in the ability of the two drugs to lower plasma PTH levels. Approximately 60% of each group met the target reduction of serum PTH. The study also failed to demonstrate a statistically significant difference between the two drugs with regards to either the incidence of a single occurrence of hypercalcemia and/or a single occurrence of elevated calcium–phosphorus product. However, when the groups were compared with regards to a secondary endpoint measuring incidence of hypercalcemia for two consecutive laboratory draws and/or calcium–phosphorus product >75 $mg^2/dL^2$ for four consecutive laboratory draws, the paricalcitol group performed better with only 18% of patients attaining these elevations versus 33% of the calcitriol patients. This suggested that paricalcitol was as effective as calcitriol in suppressing PTH, and, most importantly, it also suggested that paricalcitol was perhaps safer with regard to protecting patients from the dangers of prolonged elevated calcium–phosphorus products.

This study was followed by a landmark mortality study involving a historical cohort that compared 36-month survival among patients on long-term hemodialysis between 1999 and 2001 between patients receiving calcitriol or paricalcitol [207]. The paricalcitol-treated group had a lower mortality rate of 0.180 per person-year versus calcitriol with a mortality rate of 0.223 per person-year. Paricalcitol-treated patients also had less elevation in levels of both calcium and phosphorus at all times measured. The results of this retrospective analysis suggest a survival advantage with the second-generation paricalcitol versus its predecessor calcitriol. However, a randomized prospective study is required to confirm these important results [208].

Also approved for vitamin D supplementation in CKD for use in the United States is doxercalciferol. Limited comparative analysis has been done between this medication and its predecessors. In small trials, it has demonstrated the ability to decrease PTH levels in CKD patients with secondary hyperparathyroidism [209]. Analogs used outside of the United States include alfacalcidol, falecalcitriol, and 22-oxacalcitriol [210]. However, as with doxercalciferol, there is limited clinical data for these compounds.

## 6 TREATING THE COMPLICATIONS OF CKD: CALCIMIMETICS

As described above, the majority of patients with chronic kidney disease stages III and IV, and virtually all patients with end-stage renal disease, develop secondary hyperparathyroidism due to impaired phosphorus excretion, PTH resistance, and vitamin D deficiency. Secondary hyperparathyroidism as defined by an elevated serum PTH has been associated with numerous adverse events such as an increased risk of fractures, an increased risk of vascular calcifications resulting in calcemic uremic arteriolopathy, and calcification of soft tissues including the myocardium resulting in significantly increased cardiovascular morbidity and mortality [201]. The National

Kidney Foundation (NKF) quality guidelines aim to achieve a calcium–phosphorus product of less than 55 $mg^2/dL^2$ and a PTH less than 35–70 pg/mL, 70–110 pg/mL, or 150–300 pg/mL for CKD stages III, IV, and V, respectively [211].

Multiple studies, most notably the Dialysis Outcomes and Practice Patterns Study (DOPPS), have shown that failure of patients with end-stage renal disease to achieve the above practice guideline target ranges for calcium–phosphorus product and serum PTH are associated with significantly increased mortality [212, 213]. Additionally, there is a body of evidence suggesting that not only is failure to meet PTH goals associated with increased mortality but that the degree of increased mortality climbs with increasing levels of serum PTH [212, 213]. Unfortunately, multiple studies have shown that the majority of patients on hemodialysis fail to meet the NKF guidelines for PTH, and a substantial number fail to meet the calcium–phosphorus product guidelines as well, thus representing an area where potential treatments are urgently needed [212].

Calcimimetics are a novel class of agents that act on the calcium-sensing receptor (CaSR) on parathyroid gland cells to treat secondary hyperparathyroidism by directly reducing the secretion of PTH [214]. Cincacalcet is currently the only FDA-approved agent in this class of drugs. Multiple preclinical and clinical trials have demonstrated cinacalcet's efficacy in achieving the surrogate clinical endpoint of reduced PTH, with a currently small but growing body of evidence that its effects on secondary hyperparathyroidism correlate with reductions in fractures and cardiovascular morbidity [215]. Interestingly, the development of calcimimetics occurred concurrently with the discovery of the CaSR.

### 6.1 Discovery and Characterization of the Calcium-Sensing Receptor and Agonist Development and Mechanism of Action

The development of cinacalcet is unique in that the agent is both the first approved drug to act on a G-coupled protein receptor (GPCR) and the first drug aimed specifically at lowering PTH directly, rather than acting to lower serum phosphorus to achieve a secondary reduction in PTH [215]. Shortly after the development of the first calcimimetic agents, the receptor on which they act upon was discovered. The CaSR, a member of one of the less common GPCR families, is unique among all discovered GPCRs in that it is the only known receptor in the superfamily to bind caclium and magnesium as a first messenger. Hebert and Brown first isolated, cloned, and characterized the CaSR protein from bovine parathyroid tissue in 1993 [214]. Calcimimetics were being developed concomitantly, having been identified through molecular screening assays performed in parathyroid tissue before the discovery of the CaSR [215].

The first calcimimetics, R-467 and R-568, were identified through screening of small-molecule componds (analogs of fendiline, a calcium-channel blocker marketed as an antianginal drug) in assays of bovine parathyroid tissue [215, 216]. Several compounds, R-467, R-568, and cinacalcet, were shown to have a dose-dependent increase in cytosolic calcium, which was used as a marker of intracellular G-protein activation [215, 217]. Also, R-568 showed promise in early animal trials, mediating both a dose-dependent decrease in serum PTH and serum calcium. However, its development for humans was abandoned due both to poor oral bioavailability and extensive metabolism by CYP2D6, leading to a very high risk for drug–drug interactions [217]. Cinacalcet, developed several years later, caused a similar level of decrease in serum PTH but had greater than 70% oral bioavailability and was metabolized through multiple CYP isoforms with a lower risk for drug–drug interactions [218].

Preclinical trials have demonstrated that cinacalcet is able to reduce serum PTH in both rat models of uremia and cultured parathyroid gland cells derived from patients with severe secondary hyperparathyroidism [219, 220]. Additonally, and perhaps more of a clinically relevant endpoint, animal studies exist that suggest cinacalcet and other calcimimetics may aid in preventing extraosseous calcification (as assessed by biopsy) and renal osteodystrophy (assessed by dual-energy X-ray absorptiometry) [221, 222]. As control of serum PTH is used as a surrogate endpoint for, among other objectives, reduction in metabolic bone disease due to renal osteodystrophy, these studies are suggestive that cinacalcet may play a role in reducing fractures and calcemic uremic arteriolopathy. However, this has yet to be proven in clinical trials.

Cinacalcet's mechanism of action is unusual in several regards. Not only is it the first FDA-approved drug to act on the CaSR, it is the first approved allosteric inhibitor of any GPCR. In addition to cinacalcet's effects on the CaSR in the cells of the parathyroid gland, there is some evidence to suggest that calcimimetic agents may act on the CaSR in thyroid parafollicular C cells to release calcitonin, which would in turn lower calcium in a manner independent of PTH [223]. A documented effect on gastrin-secreting cells of the antrum may also play a role in hypocalcemia through somewhat unclear mechanisms [224]. The exact mechanism of cinacalcet's interaction with the CaSR has not been determined, largely due to the inability to date to generate crystals of the CaSR suitable for analysis. However, computerized models of CaSR based upon homology with bovine

rhodopsin have been developed, and R-568 and another calcimimetic, NPS-2143, have been hypothesized to bind residues on the second, third, and seventh transmembrane domains of CaSR [225]. Two site-directed mutagenesis experiments that show decreased affinity for calcimimetic with mutations of Glu-837 in the seventh transmembrane domain support this hypothesis [225, 226]. Future basic science research related to development of new calcimimetics may serve to further elucidate cinacalcet's mechanism of action.

### 6.2 Effects of Cinacalcet on the Calcium–Phosphorus Product and PTH

There is strong clinical trial evidence that cinacalcet is effective at reducing serum PTH and phosphorus. An analysis of pooled phase III trial data showed that 307 out of 547 patients on hemodialysis (56%) treated with cinacalcet and standard care met NKF guidelines for serum PTH versus 10% of standard care and placebo-treated patients, and 65% of cinacalcet-treated patients in the same analysis met NKF calcium–phosphorus product guidelines versus 36% with placebo [227]. The end result of these trials was that 41% of cinacalcet-treated patients met both calcium–phosphorus product and PTH guidelines versus 6% of placebo-treated patients. As of yet, open-label clinical data evaluating cinacalcet on PTH control has only been extended to 3 years, with the majority of patients who achieve NKF goals for PTH with cinacalcet able to maintain these goals through this time period [228].

### 6.3 Effects of Cincalcet on Morbidity and Mortality and Adverse Effects

While cinacalcet has repeatedly demonstrated substantial effects upon biochemical parameters, evidence for its clinical outcomes has been somewhat limited to date. An elevated calcium–phosphorus product has been repeatedly shown to correlate with increased mortality among dialysis patients, but a systematic review examining eight randomized trials of cinacalcet for patients with secondary hyperparathyroidism, five of which evaluated mortality as an endpoint, confirmed improvement in patients' PTH and calcium–phosphorus levels, but did not detect a significant improvement in any patient-level outcome, including all-cause mortality [229]. A combined analysis of four randomized, double-blinded trials evaluating cinacalcet for secondary hyperparathyroidism in patients with end-stage renal disease demonstrated a 14-fold reduction in parathyroidectomy, a 2-fold reduction in fracture, and a 40% reduction in hospitalizations for cardiovascular disease [230].

Data from phase III clinical trials suggests that cinacalcet has relatively few serious adverse effects. Gastrointestinal toxicities such as nausea, vomiting, and diarrhea were most commonly reported with rates of approximately 2–3%, with largely asymptomatic hypocalcemia observed in 1–5% of patients [231, 232]. Preliminary evidence from a phase IIIB trial suggests that taking cinacalcet with meals may ameliorate this nausea somewhat [233].

While more clinical trials with a longer period of observation are needed to evaluate the clinical endpoints of therapy with cinacalcet, particularly in regard to mortality, current data suggests that calcimimetics have potential to become a routine therapy in patients with advanced kidney disease.

## 7 SUMMARY

Renal disease, especially CKD, is increasing at an exponential pace. This makes this area of medicine attractive for the development of therapeutic agents. Specific disease states such as acute kidney injury and CKD are especially attractive given their known pathogenesis and logical targets for therapeutic agent design. The next decade will likely see a large increase in the number of therapeutic agents in this arena. One difficulty that will remain will be the design of clinical trials that can demonstrate therapeutic benefit on a feasible time scale. The development of surrogate and informative biomarkers will greatly aid this endeavor.

## 1 INTRODUCTION

Inflammatory rheumatic diseases, such as rheumatoid arthritis (RA), are associated with leukocyte ingress into the synovial tissue. In arthritis, leukocytes extravasate through the vascular endothelium. The transendothelial migration of white blood cells involve numerous inflammatory chemokines and chemokine receptors [1–14]. Angiogenesis, the growth of new capillaries from pre-existing vessels, is perpetuated during the progression of inflammatory synovitis. A number of cell-surface-bound and soluble mediators may promote neovascularization [3, 6–9]. In addition, some chemokines are also involved in synovial angiogenesis [3, 10, 15]. On the other hand, some naturally released mediators, including chemokines as well as synthetic compounds, may suppress RA-associated blood vessel formation [3, 4, 6, 8, 9, 13, 16]. There is an imbalance between pro- and anti-inflammatory chemokines, as well as angiogenic and angiostatic mediators in favor of accelerated inflammation and neovascularization in RA [1–15]. Strategies of chemokine and/or angiogenesis blockade or the administration of angiostatic agents may control synovial leukocytic inflammation and thus the perpetuation of arthritis [1–16].

In this chapter, we will briefly review the role of chemokines, chemokine receptors, and angiogenesis in the pathogenesis of arthritis. We will draw special attention to chemokines involved in neovascularization. Finally, we will describe studies on chemokine and angiogenesis targeting obtained in animal models of arthritis as well as in humans.

## 2 CHEMOKINES AND CHEMOKINE RECEPTORS IN ARTHRITIS

Chemokines drive inflammatory leukocytes into the inflamed synovial tissue [1–5, 17–19]. Chemokines have been classified into the CXC, CC, C, and $CX_3C$ supergene families. Chemokines bind to their respective receptors, which have been assigned a designation of CXCR, CCR, CR, and $CX_3CR$ [1–3, 17, 20–22]. Each chemokine has its own traditional name (see later), however, they are also considered as CXCL, CCL, XCL, and $CX_3CL$ chemokine ligands. Both designations will

**TABLE 1 Chemokines and Chemokine Receptors Relevant for Inflammatory Synovitis[a]**

| Chemokine Receptor | Chemokine Ligands |
|---|---|
| CXC chemokine receptors | |
| CXCR1 | IL-8/CXCL8, GCP-2/CXCL6 |
| CXCR2 | IL-8/CXCL8, ENA-78/CXCL5, groα/CXCL1, CTAP-III/CXCL7, GCP-2/CXCL6 |
| CXCR3 | IP-10/CXCL10, PF4/CXCL4, Mig/CXCL9 |
| CXCR4 | SDF-1/CXCL12 |
| CXCR5 | BCA-1/CXCL13 |
| CXCR6 | CXCL16 |
| CXCR7 | I-TAC/CXCL11, SDF-1/CXCL12 |
| C-C chemokine receptors | |
| CCR1 | MIP-1α/CCL3, RANTES/CCL5, MCP-3/CCL7, HCC-1/CCL14, HCC-2/CCL15, HCC-4/CCL16 |
| CCR2 | MCP-1/CCL2, MCP-3/CCL7, HCC-4/CCL16 |
| CCR3 | RANTES/CCL5, MCP-2/CCL8, MCP-3/CCL7, HCC-2/CCL15 |
| CCR4 | TARC/CCL17, CKLF1 |
| CCR5 | MIP-1α/CCL3, RANTES/CCL5, MCP-2/CCL8, HCC-1/CCL14 |
| CCR6 | MIP-3α/CCL20 |
| CCR7 | SLC/CCL21 |
| C chemokine receptors | |
| XCR1 | Lymphotactin/XCL1 |
| C-X3-C chemokine receptors | |
| CX3CR1 | Fractalkine/CX3CL1 |
| Other | |
| DARC | Duffy antigen, some CC and CXC chemokines |

[a]See text for abbreviations.

be used in this chapter. Apart from these structural differences, chemokines have also been functionally classified into homeostatic and inflammatory subclasses [5]. Although these functions may sometimes overlap, some chemokines are primarily involved in lymphocyte migration and lymphoid tissue organization, while others rather play a role in the pathogenesis of inflammatory diseases [4, 5] (Table 1).

### 2.1 CXC, CC and Other Chemokines in Arthritis

***CXC Chemokines*** CXC chemokines drive neutrophils as well as mononuclear cells into the synovial tissue [5, 17]. These inflammatory mediators also enhance leukocyte adhesion to other cells, cytoskeletal reorganization, as well as neutrophil functions [21]. Some CXC chemokines promote, while others rather suppress, synovial angiogenesis [3, 23]. As discussed later, the ELR amino acid sequence found in angiogenic chemokines may be important in synovial neovascularization [23].

Among CXC chemokines, IL-8/CXCL8, ENA-78/CXCL5, groα/CXCL1, CTAP-III/CXCL7, granulocyte chemotactic protein 2 (GCP-2)/CXCL6, IP-10/CXCL10, Mig/CXCL9, PF4/CXCL4, SDF-1/CXCL12, B-cell activating chemokine 1 (BCA-1)/CXCL13, and CXCL16 have been implicated in RA [1–5, 24–30] (Table 1).

Large amounts of IL-8/CXCL8, ENA-78/CXCL5, and groα/CXCL1 have been detected in the sera, synovial fluids, and synovial tissues of RA patients [24, 26, 27, 31–33]. Synovial macrophages are major producers of these chemokines [24, 26, 27, 33, 34]. All three CXC chemokines are inflammatory, express the ELR motif, and are proangiogenic [24, 26, 35]. Vascular endothelial cells express CXCR2, a major receptor for these chemokines [36].

CTAP-III/CXCL7 is produced by platelets, and it has been detected in RA sera and synovial tissue samples [37]. This inflammatory chemokine stimulates synovial matrix deposition, fibrosis, and angiogenesis [1, 37]. There is also abundant production of GCP-2/CXCL6 in RA [38].

IP-10/CXCL10, Mig/CXCL9, and PF4/CXCL4 exert inflammatory, but antiangiogenic, effects in RA [1, 23, 39–41]. These chemokines have been detected in the sera. Synovial macrophages and fibroblasts release these chemokines [39–41]. All three chemokines lack the ELR amino acid sequence in their structure, and they inhibit blood vessel formation in the synovium [23, 39, 41].

SDF-1/CXCL12 is in many ways a unique chemokine in RA. First, while many of other chemokines have common receptors, SDF-1/CXCL12 is a specific ligand for CXCR4. Moreover, SDF-1/CXCL12 is primarily a homeostatic chemokine involved in lymphoid organization. However, it is also involved in the development of synovial inflammation [28, 42, 43]. Synovial T cell–fibroblast interactions result in the upregulation of SDF-1/CXCL12 production. This mechanism involves IL-17 and CD40-CD40 ligand costimulation [44]. Finally, although this chemokine lacks the ELR motif, it still promotes synovial capillary formation [45]. SDF-1/CXCL12 binds to endothelial proteoglycans, and it is involved in integrin-mediated leukocyte-endothelial adhesion, osteoclastogenesis, and periarticular bone resorption [28, 46–48].

**Figure 1** Synovial endothelial cells show prominent expression of CXCR6. (Immunoperoxidase histochemistry, magnification 400×).

The crucial role of B cells in the pathogenesis of RA has been acknowledged, and numerous biologics targeting B cells have been developed recently [49–51]. Among homeostatic chemokines involved in B-cell migration and lymphoid tissue organization, some are also involved in inflammation, such as in the pathogenesis of RA. For example, BCA-1/CXCL13, the specific ligand for CXCR5, is involved in the formation of germinal centers [1, 52, 53]. On the other hand, this chemokine is also expressed by synovial fibroblasts, endothelial cells, and follicular dendritic cells within the RA synovium [54].

CXCL16, the specific ligand for CXCR6, has also been considered a homeostatic chemokine as it mediates lymphocyte recruitment and lymph node organization. In addition, large amounts of CXCL16 were detected in RA synovial tissues and fluids [29, 30]. Synovial macrophages and fibroblasts secrete CXCL16 [29, 30]. CXCL16-mediated leukocyte ingress into the synovium is mediated by the mitogen activated protein (MAP) kinase (MAPK) pathway [29].

***CC Chemokines*** Monocyte chemoattractant protein-1 (MCP-1)/CCL2, macrophage inflammatory protein 1α (MIP-1α)/CCL3, MIP-3α/CCL20, MCP-4/CCL13, regulated upon activation, normal T-cell expressed and secreted (RANTES)/CCL5, CCL18, Epstein–Barr virus-induced gene 1 ligand chemokine (ELC)/CCL19, secondary lymphoid tissue chemokine (SLC)/CCL21, thymus and activation regulated chemokine (TARC)/CCL17, pulmonary and activation regulated chemokine (PARC)/CCL18, and chemokine-like factor 1 (CKLF1) have been implicated in the pathogenesis of RA-associated inflammation [1–4, 54–74]. There is also some data available that MCP-2/CCL8, MCP-3/CCL7, hemofiltrate CC chemokine-1 (HCC-1)/CCL14, HCC-2/CCL15, and HCC-4/CCL16 may also be involved in the development of synovitis [57] (Table 1).

MCP-1/CCL2, MIP-1α/CCL3, and RANTES/CCL5 are chemotactic for monocytes, T cells, and natural killer (NK) cells [2, 58–60]. These chemokines have been detected in RA sera, synovial fluid, and tissue samples [33, 39, 58–60]. Tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1) further stimulate the release of MCP-1/CCL2 and MIP-1α/CCL3 [33, 59, 61]. MCP-1/CCL2 has been implicated in TNF-mediated osteoclast differentiation of peripheral blood monocytes. Thus, this chemokine may be involved in the development of bone erosions in arthritis [62]. A single nucleotide polymorphism in the RANTES promoter gene has been associated with disease susceptibility in Chinese RA patients [63]. Chemokine ligand 3-like 1 (CCL3L1) is encoded by a gene with variable copy numbers. Higher gene copy number of this chemokine has been associated with increased susceptibility to RA [64].

MIP-3α/CCL20, the specific ligand for CCR6, is chemotactic for mononuclear cells and has been detected in the RA synovium [1, 65]. This chemokine has been implicated in the recruitment of IL-17-producing $CCR6^+$

Th17 cells into the synovium [66]. MIP-3α/CCL2 may induce both osteoblast proliferation and osteoclast differentiation. Furthermore, increased expression of this chemokine was detected in the subchondral bone of RA patients. Thus, MIP-3α/CCL20 may exert a special role in RA-associated bone metabolism as this chemokine and the receptor activated nuclear factor kappa (RANK) ligand system collaborate in the uncoupling between new bone formation and bone resorption [67].

CCL18 facilitates T-cell attraction by antigen-presenting cells. Circulating levels of CCL18 is increased in RA patients in comparison to controls and correlate with disease activity in RA [56]. Synovial fluid neutrophils release CCL18 during their recruitment into the joints [68].

MCP-4/CCL13 is expressed in the cartilage of the RA joint. IFN-γ (interferon gamma) in combination with TNF-α and IL-1 stimulate the release of this chemokine from arthritic chondrocytes. MCP-4/CCL13 enhances the proliferation of synovial fibroblasts [69].

Some primarily homeostatic CC chemokines have also been implicated in the pathogenesis of synovial inflammation. ELC/CCL19 has been detected in RA synovial tissues [70]. The release of SLC/CCL21 is associated with the formation of germinal centerlike structures during lymphoid neogenesis in the RA synovium [54, 71]. TARC/CCL17 and PARC/CCL18 have also been implicated in T-cell recruitment into the RA synovium [72–74]. These chemokines have been detected in RA sera and synovia [72–74].

In one study, MCP-2/CCL8, MCP-3/CCL7, HCC-1/CCL14, HCC-2/CCL15, and HCC-4/CCL16 were detected in the RA synovium [57]. The function of these chemokines in RA needs to be confirmed by further studies. CKLF1 is a functional ligand of CCR4. Its expression is upregulated on activated $CD4^+$ and $CD8^+$ T cells but not on B cells in RA [55].

***C and $CX_3C$ Chemokines*** The C chemokine family contains lymphotactin/XCL1 and single C motif 1β (SCM-1β)/XCL2. The $CX_3C$ subset contains a single member, fractalkine/$CX_3CL1$ [2,3,75,76]. Lymphotactin/XCL1 involved in T-cell chemotaxis has been detected on $CD8^+$ and $CD4^+/CD28^-$ T cells in RA [77].

Fractalkine/$CX_3CL1$ is chemotactic for monocytes and lymphocytes, and it also serves as a $CD4^+$ T-cell adhesion molecule [75, 78, 79]. This chemokine induces T-cell-dependent proliferation of synovial fibroblasts [80]. It regulates RA synovial fibroblast cytoskeletal structure and migration. These processes involve JUN NH2-terminated kinase (JNK), ERK-1/2, and Akt activation [81]. In the RA synovium, macrophages, fibroblasts, and endothelial and dendritic cells produce fractalkine/$CX_3CL1$ [78, 79]. Fractalkine/$CX_3CL1$ has been associated with disease activity in rheumatoid vasculitis [82]. Interestingly, fractalkine/$CX_3CL1$ may also be involved in accelerated atherosclerosis associated with RA [83–85].

### 2.2 Chemokine Receptors in Rheumatoid Arthritis

These 7-transmembrane domain receptors are expressed on the target cells (PPT/8). Some chemokine receptors, such as CXCR2, CCR1, or CCR3, have numerous chemokine ligands, while others including CXCR4, CXCR5, CXCR6, CCR8, or CCR9 are specific receptors for a single ligand [1, 2, 17] (Table 1).

Certain chemokine receptor expression patterns have been correlated with various functions in autoimmune inflammation. For example, Th1-type inflammation in RA may be primarily associated with CXCR3 and CCR5. In contrast, asthma, a known Th2-type disease, rather involves CCR3, CCR4, and CCR8 [17, 78, 86, 87]. Regarding chemokine-induced angiogenesis, CXCR2, a receptor recognizing most $ELR^+$ CXC chemokines, is involved in inflammatory angiogenesis, while CXCR3, a receptor for most $ELR^-$ CXC chemokines may rather mediate angiostasis [1, 2, 17, 23].

Among CXC chemokine receptors, CXCR1 and CXCR2 are abundantly expressed in the RA synovium, where they recognize the most relevant inflammatory and angiogenic CXC chemokines described above [1, 2]. CXCR3 may be the most important receptor in leukocyte homing into the RA synovium [78, 86, 88]. CXCR4 is involved in SDF-1/CXCL12-derived retention of lymphocytes within the RA synovial tissue [28]. CXCR5 is expressed by T and B cells, macrophages, and endothelial cells in the RA synovium [89]. CXCR5 is involved in lymphoid neogenesis associated with antigen-induced arthritis in mice [90]. CXCR6 mediates CXCL16-induced inflammation [29]. CXCR4, CXCR5, and CXCR6 bind their respective homeostatic chemokine ligands, SDF-1/CXCL12, BCA-1/CXCL13, and CXCL16. Thus, these CXC chemokine receptors are involved in both homeostatic and inflammatory processes [1, 5, 28–30, 52].

CCR1 and CCR5 are abundantly expressed in the RA synovium [57, 78, 86, 91]. CCR1, CCR2, CCR3, and CCR5 are also expressed by articular chondrocytes [92]. CCR4 has also been implicated in leukocyte ingress into the RA joint [93]. CCR5 density on the surface of T cells may determine the intensity of synovitis in RA [94]. In some studies, a genetic polymorphism leading to the production of the truncated Δ32-CCR5 nonfunctional receptor allele was found to be protective against RA [95]. However, this protective role could not be confirmed in national cohorts [96, 97], suggesting geograph-

ical differences. CCR6, the single receptor for MIP-3α/CCL20, has also been detected on RA synovial leukocytes [65]. As mentioned above, CCR6 expressed by Th17 cells is involved in the ingress of these arthritogenic cells into the joint [66]. CCR7 has been associated with synovial lymphoid neogenesis in mice [90]. A putative chemokine receptor, CCR-like receptor 2 (CCRL2), has been identified on RA synovial fluid neutrophils and macrophages [98].

Regarding the C and $CX_3C$ chemokine receptors, XCR1 is expressed on RA synovial lymphocytes, macrophages, and fibroblasts [1, 2], while $CX_3CR1$ has been detected on macrophages and dendritic cells [76]. The expression of $CX_3CR1$ on $CD4^+/CD28^-$ T cells correlated with premature vascular damage in RA [85]. The Duffy blood group antigen receptor (DARC), which is expressed by RA synovial endothelial cells, also binds some CXC and CC chemokines [99].

### 2.3 Inflammatory and Homeostatic Chemokines in RA

*Homeostatic chemokines* are constitutively produced in lymphoid or nonlymphoid tissues. The RA synovium also contains lymphoid aggregates and germinal center-like structures. Thus, the synovium, in many ways, is similar to the skin- and mucosa-associated lymphoid tissues [5, 52–54]. Some otherwise homeostatic chemokines may also be involved in synovial inflammation [5, 52–54]. These chemokines with overlapping functions include, as discussed above, SDF-1/CXCL12, BCA-1/CXCL13, CXCL16, TARC/CCL17, PARC/CCL18, ELC/CCL19, SLC/CCL21, and maybe others [1, 5, 25, 28–30, 45, 54, 70].

Yet, most CXC and CC chemokines, as well as all C and $CX_3C$ chemokines, implicated in the pathogenesis of RA are primarily *inflammatory chemokines* [1, 2, 52]. Among these mediators, IL-8/CXCL8, ENA-78/CXCL5, groα/CXCL1, CTAP-III/CXCL7, IP-10/CXCL10, Mig/CXCL9, PF4/CXCL4, GCP-2/CXCL6, MCP-1/CCL2, MIP-1α/CCL3, MIP-3α/CCL20, RANTES/CCL5, lymphotactin/XCL1, and fractalkine/$CX_3CL1$, as well as their respective receptors, have been implicated in leukocyte recruitment during the evolution of synovitis [1–4, 54, 55].

## 3 ANGIOGENESIS IN ARTHRITIS

### 3.1 Process of Neovascularization

RA is considered an "angiogenic" disease state as there is a perpetuation of neovascularization in the synovium associated with synovial inflammation [3, 6–10]. The angiogenic process itself, its mediators and inhibitors, cellular and molecular interactions underlying neovascularization, as well as the role of angiogenesis have been extensively discussed in recent reviews [3, 6–10]. The RA synovial tissue is rich in newly formed vessels. The high turnover of capillary formation leading to increased vascular endothelial surface may enable the extravasation of inflammatory leukocytes into the synovium [3, 6–8, 10].

During the neovascularization process, angiogenic mediators activate endothelial cells in pre-existing vessels. Activated endothelial cells then release matrix-degrading enzymes, which digest the underlying basal membrane and the extracellular matrix. Matrix degradation enables the emigration, proliferation, migration, and sprouting of endothelial cells. Lumen formation within primary and further generation endothelial sprouts will lead to the development and outgrowth of new capillaries [3, 10, 11, 100, 101].

### 3.2 Angiogenic Mediators

Angiogenic mediators also involved in the pathogenesis of RA include numerous growth factors, cytokines, chemokines, extracellular matrix components, cell adhesion receptors, proteolytic enzymes, and other molecules. These mediators are released by synovial endothelial cells and macrophages [6, 7, 11, 34] (Table 2).

***Hypoxia–VEGF–Angiopoietin Pathway*** *Vascular endothelial growth factor* (VEGF) binds to heparin in the synovial matrix and plays an essential role in the induction, maintenance, and regulation of angiogenesis [15]. *Hypoxia* has been intra-articularly detected within RA joints [102], and it stimulates VEGF production in arthritis [6, 15, 103]. Hypoxia acts through the induction of the hypoxia-inducible factor heterodimer, HIF-1α/HIF-1β [12, 104]. Among other inflammatory mediators, hepatocyte growth factor (HGF), epidermal growth factor (EGF), prostaglandin $E_2$ ($PGE_2$), and nitric oxide (NO) may also stimulate VEGF release [6, 15, 16].

*Angiopoietins*, including Ang1 and Ang2, regulate endothelial functions upon stimulation by VEGF. Both Ang1 and Ang2 interact with the endothelial tyrosine kinase receptor Tie2 [14, 15]. Interactions between Ang1 and Tie2 lead to the stabilization of blood vessels [105]. Ang2 antagonizes the effects of Ang1, promotes endothelial cell motility, while inhibiting the stabilization and maturation of new capillaries [13, 15]. Survivin is an inhibitor of apoptosis, has also been implicated in VEGF-dependent neovascularization, and endothelial cell survival [15, 106]. VEGF, HIF-1, Ang1, Tie2, and

**TABLE 2 Most Important Angiogenic and Angiostatic Molecules in Arthritis[a]**

| Class | Mediators | Inhibitors |
|---|---|---|
| Growth factors | VEGF, HGF, EGF, HIF-1, PDGF, FGF-1, FGF-2, IGF-I, TGF-β | — |
| Pro-inflammatory cytokines | TNF-α, IL-1, IL-6, IL-15, IL-17, IL-18, G-CSF, GM-CSF, oncostatin M, MIF | IFN-α, IFN-γ, IL-4, IL-12, IL-13, LIF |
| Chemokines | $ELR^+$ CXC chemokines, SDF-1/CXCL12, MCP-1/CCL2, fractalkine/CXC3CL1 | $ELR^-$ CXC chemokines |
| Extracellular matrix components | Collagen, laminin, fibronectin, vitronectin tenascin | Thrombospondin 1, thrombospondin 2 |
| Cell adhesion molecules | $\alpha_V\beta_3$ integrin, E-selectin, VCAM-1, endoglin, MUC18, $Lewis^y$/H, PECAM-1 | — |
| Proteases | MMPs, plasminogen activators | TIMPs, PAIs |
| Environmental factors | Hypoxia | — |
| Vessel stabilizers, apoptosis inhibitors | Ang1-Tie2, survivin | — |
| Others | Prostaglandin E2, angiogenin, angiotropin, PAF, prolactin, substance P, endothelin-1, serum amyloid A, histamine, adenosine, erythropoietin, thrombin, etc. | DMARDs, antibiotics, thalidomide, 2-methoxyestradiol, angiostatin, endostatin, paclitaxel, troponin, osteonectin, chondromodulin, etc. |

[a]See text for abbreviations.

survivin have been detected in the RA synovial tissue [15, 107–110].

***Other Angiogenic Mediators*** Other growth factors involved in angiogenesis include fibroblast growth factor (FGF)-1, FGF-2, human growth factor (HGF), platelet-derived growth factor (PDGF), EGF, insulin-like growth factor-I (IGF-I), and TGF-β [3, 6, 7, 10]. Among pro-inflammatory cytokines, TNF-α, IL-1, IL-6, IL-15, IL-17, IL-18, granulocyte (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), oncostatin M, and macrophage migration inhibitory factor (MIF) also promote synovial neovascularization [3, 6, 7, 111–119]. TNF-α may also act via the VEGF–Ang1–Tie2 system [120], while IL-18 rather stimulates the release of angiogenic SDF-1/CXCL12, MCP-1/CCL2, and VEGF by synovial fibroblasts [116]. MIF acts via the upregulation of VEGF and IL-8/CXCL8 production [118].

Some *extracellular matrix constituents*, *cell adhesion molecules*, and matrix-degrading *proteolytic enzymes* are also involved in endothelial cell adhesion, migration, and angiogenesis. These angiogenic factors include type I collagen, fibronectin, laminin, tenascin, $\beta_1$ and $\alpha_V\beta_3$ integrins, E-selectin, selectin-related glycoconjugates including $Lewis^y$/H and melanoma cell adhesion molecule (MUC18), vascular cell adhesion molecule 1 (VCAM-1), platelet-endothelial adhesion molecule 1 (PECAM-1; CD31), endoglin, as well as some matrix metalloproteinases (MMPs), and plasminogen activators [6, 10, 34, 100, 121–123]. The $\alpha_V\beta_3$ integrin has recently drawn a lot of attention in relation to capillary formation [123]. The $\alpha_V$ subunit of this integrin is encoded by the *ITGAV* (integrin alpha-V) gene. A recent genome-wide study confirmed the association of ITGAV with susceptibility to RA [124]. The focal adhesion kinases (FAK), which are involved in signaling through the $\alpha_V\beta_3$ integrin, have been implicated in synovitis and RA-associated angiogenesis [125].

Among other important angiogenic mediators, endothelin-1, also produced by endothelial cells, induces VEGF production, endothelial proliferation, and angiogenesis [126, 127]. Increased levels of endothelin-1 have been detected in RA sera and synovia [126, 127]. Serum amyloid A (SAA), a major acute-phase reactant, stimulates synovial hyperplasia, endothelial cell migration, and capillary formation [128]. Other angiogenic factors not mentioned above in detail include $PGE_2$, angiogenin, angiotropin, platelet-activating factor (PAF), histamine, substance P, adenosine, erythropoietin, prolactin, thrombin, and many others [6, 7, 10].

### 3.3 Angiogenesis Inhibitors

Endogenous inhibitors of neovascularization suppress the effects of angiogenic mediators discussed above (Table 2). These inhibitors include cytokines, such

as IFN-α, IFN-γ, IL-4, IL-12, IL-13, and leukemia inhibitory factor (LIF) [6, 103, 129]. Tissue inhibitors of metalloproteinases (TIMP) and plasminogen activator inhibitors (PAI) antagonize the effects of angiogenic MMPs and plasminogen activators, respectively [3, 6, 7, 15, 34]. ELR-lacking angiostatic chemokines will be discussed later. Thrombospondin-1 (TSP1) blocks the activity of heparin-binding growth factors [3, 6, 7, 15]. 2-Methoxyestradiol (2ME2), a natural estrogen metabolite, inhibits neovascularization by disrupting microtubules and by suppressing HIF-1α activity [130]. 2ME2 has anti-arthritic properties in the rat adjuvant induced arthritis (AIA) model [131].

Other angiostatic compounds not yet mentioned include angiostatin (a fragment of plasminogen), endostatin (a fragment of type XIII collagen), paclitaxel, osteonectin, opioids, troponin I, and chondromodulin-1 [3, 6, 7, 103]. As angiostatin and endostatin have already been tested in therapeutic studies, they will be discussed in more detail later.

## 4 CHEMOKINES AND CHEMOKINE RECEPTORS IN ANGIOGENESIS

### 4.1 Angiogenic Chemokines and Chemokine Receptors

In general, CXC chemokines containing the ELR amino acid residue, such as IL-8/CXCL8, ENA-78/CXCL5, groα/CXCL1, and CTAP-III/CXCL7, stimulate, while $ELR^-$ CXC chemokines, such as PF4/CXCL4, IP-10/CXCL10, and Mig/CXCL9, rather inhibit neovascularization [3, 23]. As discussed above, SDF-1/CXCL12 lacks the ELR sequence; nevertheless, it still stimulates neovascularization [3, 23].

IL-8/CXCL8 is chemotactic and mitogenic for vascular endothelial cells [3, 21, 23]. ENA-78/CXCL5, CTAP-III/CXCL7, and groα/CXCL1 have also been shown to promote neovascularization [3, 6, 21, 37, 132]. The angiogenic effects of prostaglandin $E_2$ are also mediated, in part, by groα/CXCL1 [133].

SDF-1/CXCL12, despite lacking the ELR sequence, induces endothelial cell chemotaxis and angiogenesis [45, 134, 135]. SDF-1/CXCL12 acts in close cooperation with the hypoxia-hypoxia-inducible factor (HIF)-VEGF pathway. Hypoxia induces the release of this chemokine by RA synovial fibroblasts [45]. SDF-1/CXCL12 may induce angiogenesis indirectly via VEGF as this chemokine stimulates VEGF release via the phosphatidyl inositol 3 kinase (PI3K)/Akt pathway [136]. SDF-1/CXCL12 expression has also been associated with tumor neovascularization, and its expression may serve as a prognostic marker in gliomas [137].

Little is known of the angiogenic nature of CC chemokines. MCP-1/CCL2 induces endothelial cell chemotaxis and vessel formation via the CCR2 endothelial receptor [36, 138]. The angiogenic effects of MCP-1/CCL2 involve the upregulation of the Ets-1 transcription factor, as well as integrin and ERK-1/2 activation [138]. Myeloid progenitor inhibitory factor 1 (MPIF-1)/CCL23 has also been implicated in endothelial cell migration and metalloproteinase secretion [139].

As discussed above, fractalkine/$CX_3CL1$ has been implicated in angiogenesis and atherosclerosis associated with the progression of RA [76, 83, 84, 140]. $CX_3CR1$-deficient mice develop a lesser degree of atherosclerosis than do wild-type animals [140]. Moreover, an M280/I249 polymorphism in the $CX_3CR1$ gene has been associated with decreased cardiovascular risk in humans [83]. These observations may not only be important for the pathogenesis of RA, but also for understanding the mechanisms of accelerated atherosclerosis and vascular disease, leading mortality factors in RA and other inflammatory diseases.

*Chemokine receptors*, recognizing the most relevant angiogenic chemokine ligands described above, exert inflammatory and angiogenic properties in RA. For example, CXCR2, a receptor for angiogenic, $ELR^+$ CXC chemokines, is expressed on endothelial cells as well as macrophages and neutrophils in the RA synovial tissue [3, 36, 92]. As discussed above, CXCR4 is involved in SDF-1/CXCL12-mediated synovial neovascularization [28, 141]. Hypoxia induces CXCR4 expression via HIF-1 and VEGF production [142]. CXCR7, recognizing I-TAC/CXCL11 and SDF-1/CXCL12, may also be involved in synovial angiogenesis [143].

CCR2 is a receptor for the angiogenic MCP-1/CCL2 [3, 36]. In a murine model of skeletal muscle injury, CCR2-deficient animals exerted delayed muscular angiogenesis and decreased VEGF production [144]. DARC, a chemokine-binding receptor of the Duffy antigen, has been implicated in breast-cancer-associated neovascularization [145].

### 4.2 Angiostatic Chemokines and Chemokine Receptors

IP-10/CXCL10 inhibits VEGF-dependent endothelial cell migration, as well as angiogenesis [3, 21, 23, 146, 147]. On the other hand, the angiogenic VEGF induces endothelial expression of IP-10/CXCL10 [147]. Thus, IP-10/CXCL10 and VEGF may form an autocrine loop, which is involved in the up- and downregulation of capillary formation [146, 147]. Mig/CXCL9 and PF4/CXCL4 are also angiostatic [3, 23, 148]. The PF4var/CXCL4L1 nonallelic variant of the corresponding chemokine also inhibits neovascularization, as well as melanoma and

lung carcinoma proliferation [149, 150]. Among CC chemokines, SLC/CCL21 exerts angiostatic effects and inhibits tumor progression [151].

In contrast to chemokine receptors that promote chemokine-medited neovascularization, CXCR3, which binds the angiostatic chemokines IP-10/CXCL10 and Mig/CXCL9, may rather be involved in chemokine-mediated angiogenesis inhibition [3].

## 5 TARGETING OF CHEMOKINES AND CHEMOKINE RECEPTORS

Chemokines and chemokine receptors may be targeted by nonspecific strategies and by chemokine-specific approaches. Here, in vitro and animal studies, as well as a limited number of published human trials will be presented [1–4, 152] (Table 3).

**TABLE 3 Chemokine and Chemokine Receptor Targeting Strategies in RA[a]**

| Compound | Chemokine/Chemokine Receptor | Animal (A)/ Human (H) Study[b] | Reference |
|---|---|---|---|
| | *Nonspecific Blockade* | | |
| Dexamethasone | IL-8/CXCL8, MCP-1/CCL2 | H | 153 |
| NSAIDs | IL-8/CXCL8 | A | 154 |
| Sulfasalazine | IL-8/CXCL8, groα/CXCL1, MCP-1/CCL2 | H | 155 |
| Methotrexate | CCR2 | H | 157 |
| Methotrexate + leflunomide | MCP-1/CCL2 | H | 156 |
| Infliximab | IL-8/CXCL8, RANTES/CCL5, MCP-1/CCL2, groα/CXCL1, CXCL16 | H | 158–165 |
| Etanercept | CXCR3 | H | 163 |
| Antioxidants | IL-8/CXCL8, MCP-1/CCL2 | H | 166 |
| Simvastatin | IL-8/CXCL8 | H | 167 |
| Triptolide | MCP-1/CCL2, RANTES/CCL5 | A | 168 |
| Epigallocatechin-3-gallate | ENA-78/CXCL5, groα/CXCL1, RANTES/CCL5 | H | 169 |
| ML3000 | Míg/CXCL9, IP-10/CXCL10, ITAC/CXCL11 | H | 170 |
| PPARγ agonists | MCP-1/CCL2 | H | 62 |
| | *Specific Blockade* | | |
| Anti-ENA-78/CXCL5 (preventative) | ENA-78/CXCL5 | A | 172 |
| Anti-groα/CXCL1 (preventative) | groα/CXCL1 | A | 173 |
| PF4/CXCL4 peptide | PF4/CXCL4 | A | 25 |
| Anti-CXCL16 | CXCL16 | A | 30 |
| Anti-IL-8/CXCL8 | IL-8/CXCL8 | A | 171 |
| Anti-MIP-1α/CCL3 | MIP-1 α/CCL3 | A | 173 |
| Anti-MCP-1/CCL2 | MCP-1/CCL2 | A | 174–176 |
| Anti-RANTES/CCL5 | RANTES/CCL5 | A | 177 |
| KE-298 | MCP-1/CCL2 + RANTES/CCL5 | A | 178 |
| ABN912 | MCP-1/CCL2 | H | 200 |
| Antifractalkine/CX3CL1 | Fractalkine/CX3CL1 | A | 179 |
| Combined blockade | Various chemokines together | A | 180, 181 |
| CXCR2 antagonist | CXCR2 | A | 182 |
| DF2162 | CXCR1/2 | A | 183, 184 |
| Anti-CXCR3 | CXCR3 | A | 185 |
| AMD3100 | CXCR4 | A | 187 |
| FC131, other T140 analogs | CXCR4 | A | 188 |
| J-113863, other CCR1 antagonists | CCR1 | A | 189–194 |
| MetRANTES | CCR1 + CCR5 | A | 195, 196 |
| Maraviroc | CCR5 | H | 202 |
| CCR5 antagonists | CCR5 | A | 197 |
| Anti-CCR2 antibody | CCR2 | A | 199 |
| CP-481,715 | CCR1 | H | 190, 201 |

[a]See text for abbreviations.
[b]Human studies include both in vitro studies with isolated cells or histological samples, as well as in vivo studies.

### 5.1 Nonspecific Approaches

A number of antirheumatic drugs, traditional disease-modifying agents (DMARD) and biologics may influence chemokine production. Corticosteroids, such as dexamethasone, inhibit IL-8/CXCL8 and MCP-1/CCL2 production in RA patients [153]. Diclofenac and meloxicam attenuated IL-8/CXCL8 production in the rat antigen-induced arthritis (AgIA) model [154]. Sulfasalazine inhibited the release of IL-8/CXCL8, groα/CXCL1, and MCP-1/CCL2 in RA synovial explant cultures [155]. Combination of methotrexate and leflunomide decreased MCP-1/CCL2 expression in the RA synovium [156]. Methotrexate also suppressed the expression of CCR2 on RA peripheral blood monocytes, which was associated with lower disease activity [157]. Infliximab inhibited the expression of IL-8/CXCL8, RANTES/CCL5, and MCP-1/CCL2 in RA sera and synovial tissues [158, 159]. This anti-TNF agent also suppressed groα/CXCL1 and CXCL16 production in RA [160, 161]. Infliximab reduced CCR3 and CCR5 expression on RA T cells [162]. Treatment of RA patients with infliximab or etanercept resulted in the clearance of $CXCR3^+$ T cells from the synovium [163]. Anti-TNF biologics also suppressed CXCL16 expression on synovial macrophages [164]. Infliximab reduced the secretion of IL-8/CXCL8, MIP-1α/CCL3, and MCP-1/CCL2 in response to mycobacteria. Thus, the development of tuberculosis in infliximab-treated RA patients may be related, in part, to the inhibition of TNF-dependent chemokine gradients and impaired leukocyte migration [165].

Among other nonspecific non-DMARD inhibitors, antioxidants, such as *N*-acetyl-L-cysteine and 2-oxothiazolidine-4-carboxylate, inhibited the expression of IL-8/CXCL8 and MCP-1/CCL2 essenger ribonucleic acid (mRNA) by activated human synovial fibroblasts [166]. Simvastatin inhibited the release of IL-8/CXCL8 by TNF-α-stimulated RA synovial fibroblasts [167]. Triptolide, a diterpenoid triepoxide with potent anti-inflammatory effects, inhibited MCP-1/CCL2, MIP-1α/CCL3, and RANTES/CCL5 production in the rat adjuvant-induced arthritis (AIA) model [168]. Epigallocatechin-3-gallate (EGCG), an anti-inflammatory compound derived from green tea, suppressed IL-1-induced ENA-78/CXCL5, groα/CXCL1, and RANTES/CCL5 production by RA synovial fibroblasts [169]. The dual cyclooxygenase-lipoxygenase inhibitor, ML3000, downregulates the expression of CXCR3 ligands including Mig/CXCL9, IP-10/CXCL10, and ITAC/CXCL11 on RA synovial fibroblasts [170]. Activation of peroxisome proliferator-activated receptor γ (PPARγ) suppresses MCP-1/CCL2 expression in monocytes [62]. Thus, PPARγ agonists, such as glitazones, may inhibit chemokine production.

### 5.2 Specific Targeting

***Animal Models*** Neutralizing antibodies to IL-8/CXCL8 prevented arthritis in rabbits [171]. A neutralizing polyclonal anti-ENA-78/CXCL5 antibody was administered intravenously to rats using the AIA model. The antibody prevented the onset of the disease, however, it failed to control synovitis when administered therapeutically [172]. The preventative administration of an anti-groα/CXCL1 antibody delayed the onset and severity of collagen-induced arthritis (CIA) in mice [173]. A bioactive synthetic peptide derived from *PF4/CXCL4* inhibited the development of murine CIA [25]. An antibody to CXCL16 reduced the clinical arthritis score and suppressed joint destruction in murine CIA [30]. Passive immunization of mice with anti-MIP-1α/CCL3 decreased the severity of murine CIA [173]. A monoclonal antibody to MCP-1/CCL2 reduced ankle swelling and synovitis in rat CIA [174]. A novel inhibitor of endogenous MCP-1/CCL2, p8A-MCP-1, reduced cytokine expression, leukocyte infiltration, bone erosion, and improved clinical signs of arthritis in the rat AIA model [175]. A peptide inhibitor of MCP-1/CCL2 suppressed the development of arthritis in MRL-lpr mice [176]. An anti-RANTES/CCL5 antibody inhibited the progression of murine CIA [177]. KE-298, a combined MCP-1/CCL2 and RANTES/CCL5 inhibitor, attenuated the severity of rat AIA [178]. An antibody to fractalkine/$CX_3CL1$ decreased clinical severity and joint destruction in murine CIA [179].

Combined chemokine blockade has also been employed in some studies. A combination of MCP-1/CCL2 and groα/CXCL1 inhibition resulted in a greater extent of arthritis suppression than MCP-1/CCL2 blockade alone in murine AIA [180]. In the rabbit endotoxin-induced arthritis model, the combination of anti-IL-8/CXCL8 and anti-groα/CXCL1 antibodies resulted in a more pronounced inhibition of knee arthritis than did any of the two antibodies alone [181]. Certainly, an increased toxicity using combined strategies may be an important issue in the future [1].

Regarding chemokine receptor targeting, a nonpeptide oral antagonist of the CXCR2 receptor inhibited IL-8/CXCL-induced arthritis in rabbits [182]. DF2162, an allosteric non-competitive inhibitor of CXCR1/CXCR2 diminished neutrophil influx in mice and ameliorated AIA in rats [183, 184]. In the AIA model, an anti-CXCR3 antibody inhibited T-cell recruitment and disease progression [185]. Small-molecule CXCR4

antagonists gave promising results in arthritis studies [186]. Among these compounds, AMD3100 inhibited CIA in IFN-γ-deficient mice [187]. Analogs of the 14-mer peptide T140, acting as CXCR4 inhibitors, ameliorated CIA in mice [188]. Numerous CCR1 and CCR2 antagonists have been developed, and preclinical studies with chemokine receptor-deficient mice have been initiated in recent years [189–194]. For example, J-113863, a small-molecule CCR1 antagonist attenuated synovitis and joint destruction in murine CIA [194]. Met-RANTES, a CCR1/CCR5 antagonist, inhibited both murine CIA and rat AIA [195, 196]. A nonpeptide CCR5 antagonist preventatively inhibited mouse CIA [197].

Studies using chemokine receptor-deficient animals or inhibitory compounds may give different results, so early studies in this context may be difficult to interpret. For example, while a nonpeptide CCR1 antagonist improved murine CIA, CCR1-deficient mice produced more TNF-α than controls [194]. Anti-CCR2 antibody administered during the initiation of murine CIA improved the clinical symptoms [192], while CCR2-deficient animals developed more severe CIA than did wild-type mice [192, 193, 198]. The MC-21 monoclonal antibody raised against CCR2 efficiently depleted $CCR2^+$ monocytes from the blood and synovial tissue of mice with CIA. Yet, while low doses of MC-21 caused marked improvement of arthritis, high doses of this antibody rather had pro-inflammatory effects [199]. Yet, CCR blockade using antibodies or synthetic inhibitors may be promising for future therapies.

***Human Studies*** There is only a limited number of published human antichemokine or antichemokine receptor trials. ABN912, a monoclonal antibody to MCP-1/CCL2, has been tested in a randomized, controlled human RA trial. In this study, 33 patients received the active compound, and 12 received a placebo. Serial arthroscopic biopsies were performed. ABN912 treatment was well tolerated, but there was no detectable clinical benefit or significant change in synovial biomarkers [200].

A CCR1 antagonist has been tried in a 2-week phase Ib study. This inhibitor decreased the number of synovial macrophages. About one-third of the patients also fulfilled the ACR20% criteria for clinical improvement [191]. CP-481,715, another CCR1 antagonist, inhibited monocyte chemotactic activity present in human RA synovial fluid samples [190]. This compound has been evaluated in phase I for pharmacokinetics and safety [201]. Some CCR2 inhibitors have also entered clinical trials [192]. Among CCR5 inhibitors, maraviroc has been introduced to phase II–III trials in human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), as well as to phase II trials in RA [202].

## 6 TARGETING OF ANGIOGENESIS

With respect to angiogenesis and its targeting, chronic synovitis and malignancies have numerous similarities. Therefore, angiostatic compounds that undergo cancer clinical trials may soon be also tried in RA [104]. There may be two major strategies to control the perpetuation of neovascularization in "angiogenic diseases," such as RA, as well as malignancies [6, 7, 10, 104]. First, endogenous angiogenesis inhibitors described above are naturally produced in the RA synovium; however, these inhibitors should be administered in excess in order to counterbalance intensive capillary formation observed in arthritis. On the other hand, numerous small molecular synthetic compounds, as well as biologics, currently used to treat RA may, among other effects, block neovascularization as well. For example, chemokine and chemokine receptor inhibitors discussed in the previous section may also inhibit chemokine-induced angiogenesis [3, 6, 7, 103] (Table 4).

### 6.1 Animal Models

***Endogenous Inhibitors*** There has been a lot of attention regarding angiostatin and endostatin. These extracellular matrix derivatives inhibit $\alpha_v\beta_3$ integrin-dependent angiogenesis [15, 16]. Both molecules suppressed the development of arthritis in various models [3, 6, 103, 104, 203]. Angiostatin gene transfer inhibited synovitis in the mouse CIA model [104, 203]. Protease-activated kringles 1–5 (K1–5), an angiostatin analog, suppressed CIA more potently than angiostatin itself [204]. Endostatin interferes with VEGF receptor 2 signaling [15, 205]. Endostatin suppressed pannus formation and joint destruction in various rodent models [15, 206]. Intra-articularly administered kallistatin gene suppressed arthritis of the ankles in rats [207]. Arresten, canstatin, and tumstatin are derived from type IV collagen. All these molecules inhibit neovascularization [208].

Thrombospondins (TSP1 and TSP2) are angiostatic extracellular matrix molecules also produced by synovial macrophages and fibroblasts. TSPs link connective tissue molecules to integrins. A TSP1-derived peptide ameliorated inflammation and angiogenesis in peptidoglycan-induced rat arthritis [209]. TSP2 blocked capillary formation in arthritic severe combined immunodeficiency (SCID) mice [210].

Among endogenously produced cytokines, chemokines, and growth factors, IL-4 and IL-13 gene transfer attenuated synovitis and angiogenesis in the rat AIA

**TABLE 4 Possibilities of Angiogenesis Targeting in Arthritis**

| Mode of Inhibition | Chemokine/Chemokine Receptor | Animal (A)/Human (H) study | Reference |
|---|---|---|---|
| Endogenous | Angiostatin | A | 104, 203, 204 |
| | Endostatin | A | 15, 205, 206 |
| | Kallistatin | A | 207 |
| | Arresten, canstatin, tumstatin | A | 208 |
| | Thrompospondin 1 and 2 | A | 209, 210 |
| | IL-4, IL-13 gene transfer | A | 129, 211 |
| | PF4/CXCL4 | A | 25 |
| | Fumagillin analogues | A | 104, 213–215 |
| Exogenous | Classical DMARDs | H | 3, 7, 15 |
| | Anti-TNF agents (infliximab) | H | 7, 15, 120, 224 |
| | Thalidomide | A+H | 104, 216–218 |
| | VEGF inhibitors | A | 6, 104, 220 |
| | Vatalanib | H | 104, 221 |
| | HIF inhibitors (e.g., YC-1) | A | 219 |
| | Ang1/Tie2 inhibitors | A | 223 |
| | αVβ3 inhibitors (e.g., Vitaxin) | A+H | 6, 7, 104 |
| | Paclitaxel | H | 104 |
| | PPARγ agonists (e.g., pioglitazone) | H | 225 |
| | MMP inhibitors | A | 122 |
| | Endothelin-1 antagonists | H | 126 |

system [129, 211]. The administration of angiostatic chemokines to arthritis models was discussed above.

TNP-470 and PPI2458 are two angiostatic derivatives of fumagillin, a naturally occurring product of *Aspergillus fumigatus*. These compounds inhibit methionine aminopeptidase-2, an enzyme involved in neovascularization [212]. Fumagillin analogs act by the inhibition of VEGF production [6, 104]. In rodent models of RA, TNP-470 prevented arthritis when administered before the onset of the disease [104, 213]. PPI2458 suppressed synovitis and the development of joint erosions in murine CIA [214, 215].

***Exogenous Strategies*** Among nonspecific strategies, thalidomide, currently used to treat multiple myeloma, has been introduced into the treatment of RA and lupus. Thalidomide antagonizes the effects of TNF-α and inhibits angiogenesis [104, 216]. Some studies on thalidomide-mediated angiostasis gave contradictory results, as in some studies thalidomide suppressed VEGF production, capillary formation, and synovitis [104, 217], while in another rat CIA study it did not affect the release of angiogenic VEGF or TNF-α [218]. Thus, the antiangiogenic potential of thalidomide in arthritis needs further clarification. Yet, CC1069, a thalidomide analog, potently inhibited rat AIA [104].

The hypoxia–HIF pathway may also be targeted using nonspecific inhibitor compounds. YC-1, a superoxide-sensitive stimulator of soluble guanylyl cyclase is also an inhibitor of HIF-1 [219].

Regarding specific blockade of major angiogenic mediators, VEGF could be a primary therapeutic target. VEGF has been targeted by using synthetic VEGF and VEGF receptor inhibitors, anti-VEGF antibodies, as well as inhibitors of VEGF and VEGF receptor signaling [6, 104, 220]. Among VEGF receptor tyrosine kinase inhibitors, vatalanib has been tried and attenuated knee arthritis in rabbits [104, 221]. Semaphorin-3A blocks the effects of the 165-amino-acid form of VEGF (VEGF165) and inhibits angiogenesis [222].

The Ang–Tie system may also be a suitable target. A soluble Tie2 receptor transcript was delivered via an adenoviral vector to mice with CIA. The delivery of this transcript postponed the onset and attenuated the severity of arthritis [223].

Vitaxin, a humanized antibody to the $\alpha_V\beta_3$ integrin, inhibited synovial angiogenesis in rodent models of arthritis [6, 7, 104]. Some specific MMP inhibitors have been tested in angiogenesis models [122].

### 6.2 Human in Vitro and in Vivo Studies

***Endogenous Inhibitors*** Among the endogenous angiostatic molecules described above, only angiostatin and endostatin have been tried to treat human cancer [7, 15, 222]. Reports on RA studies are still awaited.

***Exogenous Strategies*** Traditional DMARDs and biologics currently used to treat RA may suppress neovascularization, as well as chemokine release described above. These agents may inhibit synovial

capillary formation by nonspecifically blocking the effects of angiogenic mediators [3, 7, 15]. For example, infliximab + methotrexate treatment inhibited systemic and synovial VEGF release, resulting in decreased synovial neovascularization [7, 15, 224]. Anti-TNF therapy of RA patients also reduced Ang1–Tie2 and survivin but stimulated Ang2 production [120].

Among other small molecular compounds, the possible use of thalidomide in human RA was described above [104, 216]. In a phase I study, paclitaxel, currently used to treat cancer, was effective and safe in RA patients [104]. Pioglitazone, an antidiabetic PPARγ agonist, is also angiostatic. This agent effectively controlled psoriatic arthritis in 10 patients [225]. Endothelin-1 antagonists currently used in the therapy of primary pulmonary hypertension, as well as scleroderma, may also exert antiangiogenic effects [126].

Regarding specific approaches, numerous small molecular VEGF receptor tyrosine kinase inhibitors are under development for the treatment of malignancies. These compounds include vatalanib, sunitinib malate, sorafenib, vandetanib, and AG013736 [104, 220]. The anti-VEGF monoclonal antibody, bevacizumab, is currently used for the treatment of colon and lung cancer [104]. There have been no completed and published studies using these VEGF inhibitors in RA. Vitaxin has also been introduced to a phase II human RA trial, but it showed very limited efficacy [104].

## 7 SUMMARY

In this review, we have discussed the potential role of chemokines, chemokine receptors, and angiogenesis in the pathogenesis of RA. A number of CXC chemokines, some CC and $CX_3C$ chemokines, and chemokine receptors may be involved in the angiogenic, as well as inflammatory, events underlying RA. In addition, chemokine and angiogenesis research may have clinical relevance for RA as well. The determination of synovial vascularity and the expression of angiogenic mediators in the arthritic synovium may have some value for determining the progression of RA. Antichemokine and antiangiogenesis targeting using either endogenously produced or exogenously administered inhibitors may control synovial inflammation.

# DEVELOPMENT OF THERAPEUTIC AGENTS: METHODS AND APPROACHES IN THE DEVELOPMENT OF VACCINES AGAINST PROTOZOAN PARASITES

Catherine Ivory and Kris Chadee
*Faculty of Medicine, Department of Microbiology and Infectious Diseases, University of Calgary, Calgary, Alberta, Canada*

## 1 INTRODUCTION

Parasitic infections make up a large percent of diseases in tropical countries and pose a significant threat to human health worldwide. Parasites are complex pathogens associated with chronic disease, high reinfection rates, and host immune depression. Furthermore, parasitic infections, unlike most viral and bacterial infections, are more complex and chronic, requiring special consideration when developing therapeutic agents. Designing strategies against parasitic infections demands that scientists address the multifactorial aspects of special pathogens. The challenge in developing therapeutic agents against parasites lies in the nature of the parasites and their close relationship with both human immunity and anthropogenic activities.

## 2 PARASITE LIFE CYCLES AND VECTORS

The leading cause of death from parasitic disease, malaria, presents unique obstacles for scientists trying to develop effective therapies [1]. *Plasmodium falciparum,* the etiological agent of malaria, is transmitted to humans via the *Anopheles gambiae* mosquito. Sporozoites are introduced into the human host and enter a hepatic cycle before being released into the blood for the erythrocytic cycle (Fig. 1). After a blood meal, the mosquito vector will ingest parasite gametocytes, which undergo a sporogonic cycle (sexual cycle) giving rise to infective sporozoites that perpetuate the life cycle. Looking at the malaria life cycle, one can identify two main obstacles: (1) the parasite develops within two different hosts and different cells, and (2) there are multiple immunologically distinct parasite stages. For this reason, scientists have concentrated their efforts on formulating a vaccine targeted at multiple stages and multiple antigens to mimic the array of immunological responses activated during a natural infection [2]. The strategy here is to find optimal antigens from different parasite stages that could mount proper immune responses at various stages in parasite development. Another problem with malarial disease is that different stages require different immunological responses to effectively eradicate the infective parasite [3]. Strong antibody responses are required to fight blood stage sporozoites as well as gametocyte transmission to the mosquito. In the liver stage, however, a strong cytotoxic T-cell-mediated response has been associated with clearance of infected host cells. Combining the need for a multiantigen approach with the need to stimulate both humoral and cell-mediated

**Figure 1** Malaria life cycle. During a blood meal an infected *Anopheles* mosquito inoculates the human host with sporozoites (2), which infect liver cells and mature into schizonts (3). Merozoites are released from the liver cells and infect erythrocytes where they undergo asexual multiplication (4). Some parasites differentiate into male or female gametocytes that are then taken up by another mosquito vector. Within the mosquito, gametocytes undergo sexual reproduction (1) forming zygotes that become oocysts releasing sporozoites. The sporozoites make their way to the salivary glands and once inoculated into a new host, the cycle is perpetuated. Vaccines for disease prevention would target pre-erythrocytic stages (2, 3), while disease reduction could be achieved with a blood-stage vaccine (4). Transmission-blocking vaccines (1) would prevent infection of a new host.

immunity, vaccinologists have turned to modern molecular and proteomic tools to address this complicated infectious disease. Proteomics has allowed scientist to identify the full repertoire of parasite proteins and the changes in protein expression with specific parasite stages. This facilitates the selection of vaccine candidates, which should be expressed on the cell surface and also serve an essential biological function. Once candidates have been chosen, these genes can be incorporated into vaccine DNA (deoxyribonucleic acid) vectors or a combination of viral vectors to induce strong T- and B-cell responses.

## 3 HOST IMMUNITY AND PARASITE ANTIGENIC VARIATION

The malaria parasite has evolved clever ways to evade the immune system or change the immune response in favor of its survival. Antigenic variation is believed to be associated with the chronic infections seen in endemic malarial regions, due to a sequential variation in polymorphic antigens expressed on the surface of infected erythrocytes [4]. One such protein is the variant surface antigen, *P. falciparum* erythrocyte protein I (PfEM1), which has been the target of many vaccination studies [5]. PfEMP1 is a surface protein involved in parasite adhesion to an array of human receptors. This molecule helps sequester the parasite in postcapillary venules, avoiding the spleen-mediated filtration of infected red blood cells. Correspondingly, by continuously changing its surface expression, the parasite evades the attack from host immune cells. There are 59 PfEMP1 variants, and each parasite expresses one variant during each cycle to improve survival. Anti-PfEMP1 immunity is known to be protective against severe forms of the disease, including cerebral and placental malaria [6]. Although PfEMP1 is a protein, which undergoes antigen variation, it may be a principle target for developing natural immunity against the parasite. A blood-stage vaccine targeted at PfEMP1 would need to induce anti-adhesion antibodies to prevent placental malaria and would have to be panreactive to protect against a range of isolates in the parasite population.

## 4 MULTIPLE STRATEGIES, DIFFERENT OUTCOMES

The complexity of the malaria life cycle introduces many possible vaccine targets, and the effects of the immunization will depend on the antigen selected. The *Plasmodium* life cycle could be interrupted at various stages (Fig. 1), and scientists have focused on three major vaccines types: (1) transmission-blocking vaccines, (2) pre-erythrocytic vaccines, and (3) blood-stage vaccines.

Transmission-blocking vaccines aim to prevent the formation of oocysts in the mosquito, thereby blocking the formation of the infective sporozoites. The prime candidate proteins for this type of vaccine are Pfs25 and Pfs28 found on the *Plasmodium* zygote [7]. The strategy in the transmission-blocking vaccine is to ensure mosquitoes acquire the antibodies against Pfs25/Pfs28 during a blood meal on an immunized human. The antibodies would then mediate complement attack on the gametocytes or block fertilization by agglutination. In conjunction with conventional malaria control pro-

grams, the transmission-blocking vaccine would reduce the incidence of new infections.

Pre-erythrocytic vaccines fall into two categories, those that target the sporozoites stages and those that target the liver stages, each of which require different immune responses. The circumsporozoite protein-1 (CSP-1) is the target of vaccines designed to induce neutralizing antibodies that would prevent sporozoites from infecting liver cells and entering the hepatic cycle [8]. This step is crucial as one sporozoite can give rise to 40,000 merozoites from which symptoms of malaria occur. On the other hand, a vaccine targeted at the liver stage would require strong cell-mediated immune responses to effectively eliminate the intracellular parasite stage. The most promising antigen target for this stage is the liver-stage antigen-1 (LSA-1) expressed on the surface of the infected hepatocyte [9]. Unlike other vaccine candidates, the LSA-1 sequence seems to be conserved between different parasite strains. In order to induce strong T-cell-mediated immunity against liver-stage malaria, vaccinologists have engaged the use of heterologous prime–boost systems [10]. The strategy in this case is to first prime the immune system with a bacterial plasmid encoding the antigen of choice and later boost the patient with a viral vector also encoding the same protein. In this way, the immune response is targeted to the encoded protein and not to the vector components. Modified viral vectors, which are nonreplicating and safe, are excellent for boosting as they induce high protein expression and presentation via major histocompatability complex (MHC) class I, thus amplifying the antigen-specific T-cell response. The principles of the strategy are to enhance T-cell-mediated responses and to generate memory T cells to the vaccine antigen. Clinical trials with RTS,S/ASO2D, encoding the CSP-1, have demonstrated that the prime–boost method was safe, tolerated, and immunogenic in young children [11].

The last type of malaria vaccine is a blood-stage vaccine, targeting the intracellular erythrocytic stage. The parasite resides inside the red blood cell and is hidden from the immune system. Since erythrocytes do not express MHC class I or II molecules, the desired immune response at this stage is antibody mediated. Vaccine trials for blood-stage malaria target the apical membrane antigen (AMA-1) or the merozoite surface protein (MSP-1). Antigen-specific antibodies mediate antibody-dependent cytotoxicity and complement activation [12]. Immune responses at this stage of the parasite cycle are designed to reduce symptoms of disease, while pre-erythrocytic vaccines are aimed at disease prevention. It is important to consider the interaction of the human immune system with the malaria parasite, as different stages induce different responses and require special attention while developing a vaccination strategy. Perhaps the ultimate vaccine would incorporate antigens to all these stages and induce strong antibody as well as cell-mediated immunity to the parasite.

## 5 *ENTAMOEBA HISTOLYTICA*: THE IDEAL PARASITE?

Parasites include a diverse array of organisms, ranging from multicellular worms to microscopic single-celled amebas. In fact, parasite biology can range from relatively simple demands to complex multiple-host life cycles. Unlike the complexity seen with the malaria parasite, *E. histolytica* presents a simple survival scheme. *Entamoeba histolytica* is an enteric protozoan parasite responsible for the human disease known as amebiasis. The disease is acquired through the ingestion of an infective cyst stage found in contaminated food or water. The cyst migrates to the large intestine where it gives rise to the mobile trophozoite stage responsible for the onset of amebic colitis (Fig. 2). In some cases of amebic infection the ameba can breach the intestinal lining and disseminate via portal circulation to the liver,

**Figure 2** The *E. histolytica* life cycle. The infective cyst stage is ingested by a human via contaminated food or water (1). The cysts in the gut give rise to mobile trophozoites, which colonizes the large intestine (2). In the event of invasive amebiasis, the parasite breaches the gut lining and is disseminated to the liver, causing amebic liver abscess (3). New cysts are formed in the colon and passed into the environment with feces, thus perpetuating the life cycle. An amebiasis vaccine would target the trophozoite stage (2), inhibiting parasite colonization with adherence blocking antibodies.

where they can cause contained amebic liver abscesses. Humans are the only relevant hosts for this parasite, and, unlike malaria, this organism cycles between two stages, with only the trophozoites being pathogenic. *Plasmodium* is an intracellular parasite, which has an array of immune evasion mechanisms, while *Entamoeba* is an extracellular pathogen, with no known antigenic variation or obvious immune evasion methods. Consequently, the focus of therapies against amebiasis is aimed at the trophozoite stage, using chemotherapy that can effectively kill the parasite and the development of vaccines to block trophozoite colonization.

Amebiasis is a cosmopolitan disease; however, it is endemic in developing countries and afflicts an estimated 50 million people [13]. Although chemotherapy (metronidazole) against amebiasis is effective, access to treatment is limited and infections rates remain high in these endemic regions. There is a need to develop preventative or prophylactic therapies to decrease the incidence of disease and mortality. Amebiasis could be eradicated with the implementation of proper sanitation in these endemic areas; however, the social changes and public health interventions required for such a task are not foreseeable in the near future. Based on these limitations, vaccination is a more plausible and cost-effective way of preventing amebiasis. When addressing the possibility of a vaccine against an infectious agent such as *E. histolytica,* it is important to consider several key features of the disease: (1) the existence of natural acquired immunity, (2) the pathogenesis of disease, and (3) the prevalence of amebiasis and the target population.

## 6 IMMUNITY TO *E. HISTOLYTICA*

It is necessary to determine the hallmarks of natural immunity to *E. histolytica* in humans to design a vaccination strategy with the desired immune indicators. The distinct clinical manifestations of disease with *E. histolytica*, mainly amebic colitis and amebic liver abscess, also have distinct immune responses. Amebic colitis is characterized by a prominent pro-inflammatory response, whereas amebas in the liver do not cause hepatitis but an abscess surrounded by connective tissue to segregate healthy liver parenchyma from diseased areas. Despite this pathophysiological difference, there are many common immune components active during amebic colitis and amebic liver abscess.

The parasite first encounters intestinal epithelial cells, and, therefore, gut inflammation in amebic colitis is the result of epithelial cell release of pro-inflammatory cytokines interleukin-8 (IL-8) and IL-1β [14]. These mediators can attract neutrophils and macrophages to the site of infection. Neutrophils are also the first host defense cell to contact amebas in the liver, indicating recruitment of these cells to the site of infection [15]. In the case of amebic colitis, however, it would appear that neutrophil recruitment exacerbates inflammation through the release of their toxic contents [16]. Although inflammation in amebic colitis definitely contributes to tissue damage, it may also be required to limit infection.

Macrophages have been associated with cell-mediated immunity against *E. histolytica*. The activation of these effector cells depends on environmental cues and the inflammatory stimuli. The major priming signal for macrophage activation is interferon-γ (IFN-γ). Naïve bone-marrow-derived macrophages exposed to *E. histolytica* proteins demonstrate increased expression of *c-fos*, which is involved in activation, and increased tumor necrosis factor-α (TNF-α) messenger ribonucleic acid (mRNA) [17]. Macrophages can effectively kill amebas in vitro in a nitric oxide (NO)-dependent manner [18]. TNF-α production by activated macrophages can enhance inducible nitric oxide synthase (iNOS) mRNA for increased NO production [19]. The ability of *E. histolytica* proteins to stimulate TNF-α could be central in activating primed macrophages for amebicidal activity. In the case of amebic liver abscess formation, IFN-γ is important to prime macrophages for activation, and iNOS is essential to mount a proper amebicidal response. In fact, it has recently been reported that higher IFN-γ production is correlated to a reduced risk of amebic disease in humans [20]. IFN-γ is a key pro-inflammatory cytokine regulating macrophage activity against the invading parasite.

Most importantly, in terms of human immunity to *E. histolytica*, the presence of antilectin mucosal IgA has been associated with a reduced risk of infection in endemic areas [21]. Recent epidemiological studies have illustrated the importance of mucosal immunity in resistance to *E. histolytica* infection. These studies were conducted in preschool Bangladeshi children where there is a 55% *E. histolytica* infection rate and colitis is diagnosed in 4% of these cases of infection [22]. These studies determined that children with antiamebic stool IgA had 64% fewer infections, and the occurrence of these antibodies was thought to prevent parasite colonization [21]. In most cases the antiamebic stool IgA was detectable near the time of resolution. While the presence of stool IgA was associated with protection from reinfection, the absence of serum IgG against the parasite was also associated with innate resistance to *E. histolytica* infections [22]. Upon closer examination it was determined that the presence of stool IgA specifically against the Gal-lectin was protective, associated with 86% less new infections over the following year.

Protective immunity after amebic infection appears to be mediated by mucosal IgA against *E. histolytica*. It is not surprising that mucosal IgA antibodies directed against the parasite provide protection since the disease is acquired in the gastrointestinal tract. These findings are essential and determined that acquired immunity in humans is mucosal. A vaccine for amebiasis should logically try to stimulate the gut-associated lymphoid tissue and induce sufficient mucosal responses, specifically secretory IgA against the parasite. It is also important to consider the role of the inflammatory response in amebiasis and design a vaccine that could provide both the mucosal antibodies and protective Th1 cytokines associated with reduction of disease.

## 7 PATHOGENESIS OF AMEBIASIS

The pathogenesis of amebiasis is a complicated process involving three distinct stages and multiple parasite virulence factors. The parasite is acquired by the ingestion of the cyst stage in contaminated food or water. However, infection and disease progression requires these three stages: colonization, mucus depletion, and damage of host cells. The parasite must overcome the innate mucosal defenses of the host, including both physical barriers and immune mechanisms.

The first step in pathogenesis of amebiasis is the colonization of the host's colon by the mobile amebic trophozoites. The human gastrointestinal tract is protected by a gelatinous mucus layer, which is composed of carbohydrate-rich mucin molecules. A single molecule, the Gal-lectin, mediates colonization by the parasite to the mucin layer. The Gal-lectin binds to galactose and *N*-acetyl-D-galactosamine residues of colonic mucins [23]. The Gal-lectin is a major surface protein that contains the carbohydrate recognition domain involved in adherence to the terminal sugar moieties of colonic mucins and host cells [24]. Adherence to colonic mucins allows the parasite to multiply and prevents it from being carried away, thus establishing infection. At the same time, however, mucins provide a protective role, preventing parasite contact with underlying epithelial cells.

In the second stage, the parasite overcomes this physical barrier by both depletion and destruction of mucins. Colonic mucins are produced by goblet cells in the intestine, and it is believed that *E. histolytica* can induce hypersecretion in these cells. The parasite can induce significant mucous secretion from goblet cells. In fact, studies in gerbils suggested that the trophozoites release a mucous secretagogue, which would lead to the eventual depletion of mucin secretion from goblet cells [25]. In conjunction with mucous depletion is the process of mucous destruction by the parasite, which occurs through the activity of cysteine proteases. It has specifically been shown that *E. histolytica* cysteine protease 5 (EhCP5) can directly cleave the C-terminus of the MUC2 polymer, thus destroying the gel-forming properties of mucins [26].

Upon removal of this protective mucous barrier, the parasite comes in contact with host intestinal epithelial cells. As mentioned above, parasite adherence is mediated by the Gal-lectin, and so this molecule is also required for binding to host cells. Adherence to host cells is followed by cytolysis, thus leading to tissue destruction from which the parasite gets its name. The importance of Gal-lectin-mediated cell contact has been illustrated in vitro with a Chinese hamster ovary (CHO) cells deficient in terminal galactose/*N*-acetyl galactosamine residues, which were resistant to amebic cytolytic activity compared to normal cells [27]. It has also been demonstrated in vivo that Gal-lectin-deficient trophozoites are less virulent, causing very little pathology [28]. Cytotoxicty is observed within 5–15 min after parasite contact and involves both apoptosis and necrotic cell death [29, 30]. This cell death is thought to be associated with the action of amebapores [31], pore-forming proteins that are inserted by the trophozoites into the host cell membrane upon contact and cause cell lysis.

Understanding the events in the pathogenesis of amebiasis helps in vaccine design by identifying target antigen and target areas to interrupt parasite life cycle. In the events described above it is made apparent that the Gal-lectin molecule mediates all three major steps in disease progression. The important role of the Gal-lectin in *E. histolytica* biology makes this antigen a prime candidate for an amebiasis vaccine. Furthermore, amebic infection is determined by the parasite's ability to first colonize the human intestine, and blocking this step with a vaccine that induces Gal-lectin-specific mucosal antibodies would drastically reduce the incidence of invasive disease.

## 8 PREVALENCE OF DISEASE AND TARGET POPULATION

The World Health Organization estimates that *E. histolytica* infects 50 million people worldwide and leads up to 100,000 deaths a year [13]. *Entamoeba histolytica* is most prevalent in subtropical areas such as Mexico, Africa, India, and South America. Higher prevalence in those areas is due to lower standards of sanitation leading to greater contamination of food and water. All races are equally susceptible to infection, but high-risk groups include travelers to endemic areas, homosexuals [32], and immunocompromised individuals. Following

this last point, severe cases of amebiasis are more common in young children, pregnant women, and elderly individuals.

The majority of infected individuals remain asymptomatic, with the parasite residing in the large intestine as a commensal. For yet undetermined reasons, an estimated 10% of infected humans will develop symptoms of invasive disease. The factors that determine whether an infected individual will develop invasive disease are not known. A recent study conducted in an endemic area of Bangladesh suggests that there may be an association between the parasite genotype and risk of complication [33]. There may also be host factors that could predict the outcome of disease; however, these remain unidentified to date. Considering these yet unsolved mysteries regarding the onset of invasive disease, it would be most useful to test a potential vaccine candidate in the population for which it is intended. Several factors could influence the immune response to a prospective vaccine, including gut flora, environmental factors, nutrition, and concurrent or past infections with *E. histolytica* or other gut pathogens.

## 9 VACCINE DESIGN

### 9.1 Choosing a Candidate Vaccine Antigen: Gal-lectin

One of the most well-studied molecules of *E. histolytica* is the galactose/*N*-acetyl-D-galactosamine-specific lectin (Gal-lectin). Gal-lectin is a transmembrane 260-kDa heterodimer composed of a 170-kDa heavy subunit linked by disulfide bonds to a 35-kDa light subunit [34]. This molecule is a prime candidate for an amebiasis vaccine. Gal-lectin meets many criteria for a vaccine antigen. First, it is a cell surface molecule highly exposed to host immune cells and is known to have strong immunogenic properties. Second, Gal-lectin is a parasite virulence factor without which the parasite loses its pathogenicity [28]. Third, Gal-lectin is a highly conserved antigen and shows very little genetic variability. *Entamoeba histolytica* does not have a sexual cycle and therefore appears to be clonal with closely related organisms found throughout the world [35].

### 9.2 Gal-lectin Immunogenicity

Gal-lectin, specifically the heavy subunit, is a highly conserved antigen and is recognized by human immune sera from patients throughout the world [36]. In fact, 95% of sera from amebiasis patients have antibodies against Gal-lectin [37], and it is the major antigen recognized by pooled human immune serum. Most importantly, the presence of antilectin mucosal IgA has been associated with a reduced risk of infection in endemic areas [21]. Acquired resistance to *E. histolytica* infection was linked to these protective intestinal IgA antibodies that are directed against the carbohydrate recognition domain of the Gal-lectin.

In addition to humoral responses, Gal-lectin also demonstrates immunogenicity in cell-mediated responses. Peripheral blood monocytes isolated from individuals previously exposed to *E. histolytica* respond to Gal-lectin, demonstrating the potency of this antigen [38]. It was also observed that T cells treated with Gal-lectin for 5 days in vitro became amebicidal, while cells from control individuals did not. Another study looked at the specific Gal-lectin region involved in this T-cell response. These studies illustrated that there may be important T-cell epitopes on the Gal-lectin antigen responsible for the induction of cell-mediated immunity against *E. histolytica*.

Gal-lectin-mediated cell immune responses have extensively been studied in macrophages. These specialized antigen-presenting cells play an important role in innate and adaptive immune responses, specifically in pathogen elimination. Activated macrophages are able to kill *E. histolytica* trophozoites in vitro [39]. Stimulation of murine bone-marrow-derived macrophages with Gal-lectin induces the production of TNF-α and IL-12 [19, 40]. This TNF-α production is mediated by the cysteine-rich region as monoclonal antibodies (mAbs) against amino acids 596–1082 could effectively block this macrophage stimulation. In another study it was demonstrated that Gal-lectin could also induce NO production in IFN-γ-primed murine macrophages. Macrophages were amebicidal when treated simultaneously with IFN-γ and Gal-lectin, and this cytotoxic effect could be inhibited by mAbs against amino acids 596–818 of the cysteine-rich region.

### 9.3 Targeting the Right Epitopes

Gal-lectin's primary role is to mediate parasite binding to host glycoconjugates with high affinity. By this mechanism Gal-lectin mediates colonization of the human colon by binding to colonic mucin. Gal-lectin also mediates binding to target host cells and confers complement resistance via its CD59-like domain [41]. Carbohydrate recognition has been mapped to the heavy subunit of Gal-lectin. The carbohydrate recognition domain (CRD) has been determined with the use of mAbs that map to epitopes on the cysteine-rich region of the extracellular domain on the heavy subunit. These mAbs could block parasite-binding activity and correspond to amino acids 895–998 [42]. This sequence of 104 amino acids is highly conserved among products of the *hgl*

gene family. It is obvious from these studies that carbohydrate recognition occurs within the cysteine-rich region of the heavy subunit, and this should be considered in vaccine design. During the mapping of the CRD, it was observed that certain mAbs (3F4 and 8A3) could enhance Gal-lectin-mediated binding to CHO cells [43]. The Fab fragments alone could induce this effect; therefore, it was not due to antibody clustering of the lectin. In fact, the mAb binding seemed to be changing Gal-lectin to a more active conformation. The regulation of Gal-lectin conformation is thought to be mediated by inside-out signaling. The Gal-lectin cytoplasmic tail contains regions of identity with the cytoplasmic tail of β2 intergrin-like domains, and this could mediate the inside-out signaling [44].

Conformational changes in Gal-lectin are important in designing an amebiasis vaccine, since some epitopes may be hidden while others may actually exacerbate disease by enhancing parasite adherence. Parasitologists are able to grow *E. histolytica* trophozoites in the laboratory, and isolation of the native Gal-lectin protein is possible; however, on large scale purifying native amebic proteins would not be cost effective. Expression of amebic antigens in prokaryotic or plant systems has proven to be successful and offer an alternative for large-scale vaccine production. The advent of recombinant vaccines such as hepatitis B has established large-scale production methods that could be adapted for new developing vaccines. Native Gal-lectin and recombinant forms containing the CRD have been tested as amebiasis vaccines (Table 1).

### 9.4 Animal Models of Amebiasis and Gal-Lectin Vaccine Trials

*Entamoeba histolytica* is acquired through the ingestion of the infective cyst stage from which arise the mobile trophozoites that cause disease in humans. Unfortunately, to date there is no laboratory method to cultivate this infective cyst stage, and, therefore, natural infection cannot be recreated in animal models. All experimentally induced amebiasis methods currently available require administration of live *E. histolytica* trophozoites into the target tissue. Although this procedure does not represent the natural course of infection, experimental amebiasis models are useful to test vaccine formulations and provide evidence of the efficacy of the immune responses produced.

One of the first and most frequently used models is the gerbil (*Meriones unguiculatus*) model for intestinal amebiasis and amebic liver abscess. Male gerbils are anesthetized for laparotomy, and *E. histolytica* trophozoites are injected directly into the left liver lobe to induce abscess. The gerbil model of amebic liver abscess is highly reproducible and the main model to study extraintestinal amebiasis. The main disadvantage of this

model is the lack of immunological reagents to characterize the host response to *E. histolytica* infection. Mice disease models are advantageous because of the wide range of reagents available to dissect the immune response as well as various gene knockout strains that can allow the study of specific immune components in disease pathogenesis. In the case of amebiasis, mice have demonstrated strain-dependent resistance to *E. histolytica* and have made the development of reliable mice models difficult [45]. Nonetheless, it has been shown that C3H/Hej and CBA/J mouse strains are susceptible to intestinal amebiasis, while C57BL/6 and BALB/c mice are naturally resistant. It is also important to note that mice deficient in IL-12, IFN-γ, and NO are resistant to intestinal amebiasis [46]. The nature of resistance in these mice strains is unclear and complicated. Neutrophil depletion leads to increased susceptibility to intestinal amebiasis in a normally partially resistant CBA mouse strain but had no effect on the resistant C57BL/6 mice [47]. A recent study has examined the factors involved in mouse resistance using bone marrow chimeras from resistant and susceptible mice. Shinjiro Hamano et al. [48] put forth a two-tier resistance model from their chimera studies, suggesting that the first line of resistance is conferred by the intestinal epithelial lining and the second by the underlying immune cells. The authors also reported the contribution of IL-10 to innate resistance, suggesting that the cytokine had physiological effects on intestinal epithelial cells inducing a protective barrier to infection.

The susceptible C3H/Hej mice have been used as model for intestinal amebiasis [46]. These mice are anesthetized and a laparotomy is performed to expose the cecum in which the live *E. histolytica* trophozoites are injected. These mice develop chronic nonhealing lesions in the cecum characterized by mast cell infiltration and cecitis was marked by IL-4 and IL-13 cytokine production. Depletion of CD4+ T cells decreased parasite burden and greatly reduced inflammation associated with mast cell infiltration. In this model CD4+ cells exacerbated diseases, demonstrating the importance of host immune cells in disease progression. The disadvantage of this model is that it has a 60% infection rate and therefore requires a larger number of animals for reproducibility. In order to examine the role of T and B cells in immunity to amebiasis, severe combined immunodefient mice (SCID) have been used as a model for amebic liver abscess [49]. SCID mice develop abscesses characterized by neutrophil infiltration that surround necrotic areas containing trophozoites. The abscess is clearly separated from healthy hepatic tissue by a ring of inflammatory cells and fibrosis.

Although the C3H/Hej and SCID mouse models can illustrate immune parameters because of the availability of immunological reagents, these are limited in their ability to truly discern the interaction with a human parasite. The SCID-HU-INT model, using a human intestinal xenograft, was developed to address this issue [50]. A piece of human intestinal tissue is grafted onto the subcapsular region of a SCID mouse and allowed to integrate for 8 weeks. The graft area is then infected with *E. histolytica* and develops severe inflammation characterized by neutrophil infiltration and IL-8 as well as IL-1β secretion from epithelial cells. This model is useful to study the human immune responses to *E. histolytica*. However, it is not a tool that every laboratory can use because it requires access to human tissue and also requires 2 months before experiments can take place.

### 9.5 Vaccine Trials

Acquired immunity to invasive amebiasis has been achieved repeatedly either using total amebic antigen immunizations or drug-cured animals resistant to secondary infection. Based on the animal and epidemiological evidence that acquire immunity occurs against *E. histolytica*, the feasibility of an amebiasis vaccine has become more evident. To date only a few amebic proteins have been considered as vaccine candidates, including the serine-rich *E. histolytica* protein (SREHP), the 29-kDa cysteine-rich protein, and Gal-lectin [51]. SREHP is a surface membrane protein whose function remains unclear but that demonstrates immunogenicity both in humans and in animal models. The 29-kDa cysteine-rich protein is believed to be involved in parasite detoxification of hydrogen peroxide and also demonstrates high immunogenicity with 80% of patients with amebic abscess having antibodies against this antigen [52]. Gal-lectin, however, is the most promising vaccine candidate because it is an essential parasite virulence factor and extremely immunogenic. The central role of Gal-lectin in *E. histolytica* pathogenesis makes it a prime target for the host's immune system. Several immunization trials have used the native Gal-lectin or recombinant portions of the molecule and exhibited some degree of protection against amebic abscess or intestinal disease (Table 1).

The protective effects of Gal-lectin were first reported [53] where the native molecule was used with Freund's adjuvant to immunize gerbils. All immunized gerbils developed high titers of anti-Gal-lectin antibody capable of blocking parasite adherence in vitro. Combining the intraperitoneal and subcutaneous immunization, Gal-lectin demonstrated 67% vaccine efficacy, compared to sham immunized controls. The immunized gerbils that were not protected developed significantly larger abscesses than controls; however, there was no correla-

tion between antibody titers and protection. The formation of larger abscesses in these animals was believed to be due to some immunosuppressive effects of Gal-lectin. This initial vaccination study revealed that Gal-lectin was a potent vaccine antigen but that it could also exacerbate disease in some instances. This brought about the notion that different regions of Gal-lectin may be responsible for the protective and the deleterious effects observed after challenge infections. Many future vaccination trials examined the protective effects of subunits of Gal-lectin [54–56]. A particularly interesting study by Lotter et al. determined the protective and exacerbating regions of Gal-lectin using four recombinant proteins corresponding to four main regions of the heavy subunit [57]. The four proteins included the cysteine-poor region [r170CP 1–143 amino acids (aa)], the pseudorepeat region (r170PR 437–624 aa), and two cysteine-rich regions (r170CR1 799–939 aa) and (r170CR2 940–1053). Gerbils were immunized and the formation of amebic liver abscess compared for each of the four recombinant proteins. Immunization with the r170CP was found to exacerbate disease and this due to the antibody binding the amino terminal of the molecule. The r170CR1 had no effect, while both r170PR and r170CR2 demonstrated protection against amebic liver abscess. Passive transfer of rabbit immune serum for r170CR2 and r170PR into SCID mice also protected against abscess formation. It was also observed that 100% of serum samples from human patients with amebic disease reacted with the exacerbating r170CP protein, whereas 78% asymptomatic patient serum recognized the protective r170CR2 protein. This study identified the region of Gal-lectin involved in protection from disease.

Although the cysteine-rich region of Gal-lectin was protective against disease progression, at this point it was unclear whether the same effects would be observed at the intestinal level. Houpt et al. [60] showed that both purified native Gal-lectin and a recombinant portion (LecA 578–1154 aa) could protect against intestinal amebiasis in the C3H/Hej model. The mice were immunized intranasally with either native Gal-lectin or LecA adjuvated with cholera toxin and boosted by intraperitoneal injection with Freund's adjuvant and the vaccine. The mice were then challenged by intracecal injection of live *E. histolytica* trophozoites and assessed for intestinal pathology by histological damage scores. The native Gal-lectin immunizations conferred protection with a vaccine efficacy of 84–100% while the recombinant LecA had a vaccine efficacy of 91 and 34% in the first and second trial, respectively. Protection in this study was associated with the presence of prechallenge fecal anti-Gal-lectin IgA. The vaccination trial demonstrated that Gal-lectin and LecA could prevent *E. histolytica* colonization but did not seem to reduce disease severity in those unprotected animals.

Another revolutionary vaccination strategy, DNA vaccines, can induce both humoral and systemic immune responses by directly transfecting host cells with plasmid encoding the vaccine antigen. Recently, in our laboratory a codon-optimized DNA vaccine encoding the cysteine-rich region (894–1081 aa) of Gal-lectin was developed and administered to BALB/c mice by intradermal immunization [62]. This DNA vaccine induced Gal-lectin-specific IgG2a Th1-type antibodies that could reduce parasite adherence to CHO cells. Cell-mediated responses were also induced by Gal-lectin DNA vaccination, characterized by T-cell proliferation to Gal-lectin.

### 9.6 Improving Vaccine Delivery and Efficacy

Amebiasis is a gastrointestinal disease, and the strategy for an effective vaccine is to stimulate the gut immune system and block parasite colonization. Several attempts have been made to improve vaccine delivery and efficacy with Gal-lectin. *Salmonella* strains have been used as a means of delivering antigens to the gut-associated lymphoid tissue as these bacteria effectively invade Peyer's patches. This strategy could effectively induce both mucosal and systemic immunity, which could prevent parasite colonization and reduce disease severity. *Salmonella dublin* expressing the LecA fragment of Gal-lectin was used as an oral vaccine vector [56]. Oral immunization of gerbils with $10^8$–$10^{10}$ bacteria three times provided some protection against amebic liver challenge infection, reducing abscess size compared to controls. This study demonstrated that oral immunization conferred systemic immunity against *E. histolytica*. The bacterial vector strategy was repeated recently with *Yersinia enterocolitica* expressing Gal-lectin fused to the outer protein [61, 63]. Live attenuated *Yersinia* was administered orally to gerbils that were then challenged for amebic liver abscess. Oral immunization with this vector also protected gerbils against amebic liver abscess formation.

Recently, as our knowledge about innate immunity increases, the choice of adjuvant in vaccine development has become as important as the choice in vaccine antigen. It is imperative that the vaccine formulations induce the correct response to ensure protection. Dendritic cells have a crucial role in this vaccine response as they direct the capture of antigens and the ensuing responses. In fact, antigen capture in the absence of concurrent dendritic cell maturation leads to immune tolerance and not immunity. An emerging field in vaccination research is the use of toll-like receptor (TLR) ligands in immunizations to ensure the proper

adjuvant response. CpG-oligodeoxynucleotides (CpG-ODNs) are recognized by TLR9, expressed on subsets of dendritic cells and induce maturation as well as potent Th1 cytokine production [64]. CpG-ODNs have been used in animal models of various diseases and shown consistent adjuvant properties both with parenteral and mucosal vaccines [65]. Ongoing clinical trials with CpG-ODN have investigated the use of these TLR ligands as adjuvants and demonstrated that they are well tolerated by humans and produce the desired improved immune responses. Gal-lectin is a prime candidate for an amebiasis vaccine, and given the immunogenic Th1 response and protection observed to date with Gal-lectin, efforts should be made to improve vaccine efficacy.

The development of mucosal vaccines in humans has been limited by the lack of safe yet effective mucosal adjuvants. The gold standard mucosal adjuvant in animals is the cholera toxin; however, it is too toxic for use in humans. In order to address the feasibility of a mucosal amebiasis vaccine for potential use in humans, we tested an intranasal Gal-lectin vaccine using CpG-ODN as adjuvant [66]. We chose Gal-lectin as a protective amebic antigen and chose CpG-ODN as a potent Th1-inducing nontoxic adjuvant. CpG-ODNs containing nuclease-resistant phosphorothioate backbones are coadministered with the vaccine antigen to induce specific immunity. We tested the native Gal-lectin and CpG-ODN vaccine in the gerbil model of amebic liver abscess and in the C3H/Hej mouse model of amebic colitis. Repeated intranasal immunization followed by one booster intraperitoneal injection resulted in the production of both anti-Gal-lectin IgG and IgA antibodies capable of blocking parasite adherence in vitro. The immunized animals produced more IFN-γ than sham immunized controls and had Gal-lectin-specific lymphocytes capable of proliferating in response to Gal-lectin exposure. More importantly, immunized gerbils were protected from subsequent challenge infection and did not develop amebic liver abscesses. Several properties of Gal-lectin and CpG-ODN contributed to the efficacy of this vaccine. CpG-ODN adjuvant primed the immune response to the coadministered Gal-lectin, and both components are strong Th1 inducers activating immune cells in a pro-inflammatory fashion. The intranasal administration proved to be successful in inducing the desired mucosal IgA response, with the production of Gal-lectin-specific fecal antibodies. Although we did not correlate these anti-Gal-lectin IgA with protection from intestinal disease in the mouse model, it is interesting to note the presence of these specific antibodies after immunization and the epidemiological evidence that in humans IgA is protective. Protection could be correlated, however, with elevated levels of IFN-γ in the gerbil model of amebiasis. These findings underline the importance of vaccine design and the need to optimize the desired responses to provide both mucosal and cell-mediated immunity to *E. histolytica*. In this way a vaccine capable of inducing both mucosal and systemic immunity could prevent colonization in an antibody-mediated fashion and prevent invasive disease mediated by a strong Th1 response to Gal-lectin.

## 10 CONTINUING RESEARCH EFFORTS

In order to address the challenges in vaccine development continued research about the nature of protective immunity in amebiasis and the factors that determine amebic invasion are required. A new bioinformatics resource center, *Pathema,* created for category A–C pathogens described by the National Institute of Allergy and Infectious Diseases, includes *E. histolytica*. This service provides scientists with the tools to study *E. histolytica*, including protein cataloging, functional genomics, and comparative analyses. The completion of the *Entamoeba* genome was a keystone event in amebiasis research, allowing researchers to probe the genome to identify differences in virulence and immune targets [67]. The *Entamoeba* genome is readily available on *Pathema* and researchers can exchange protocols and new findings. This informatics center encourages the type of collaborative work that could help establish the groundwork for future amebiasis therapies.

Continued vaccine research in rodent models is essential to help elucidate the immune mechanism involved in protective immunity; however, these studies cannot predict the efficacy of a vaccine in humans. Nonhuman primate models are a good starting point for testing vaccines for human use. The specificity of *E. histolytica* to humans makes experimental amebiasis difficult to study; fortunately, it has been demonstrated that baboons can be naturally infected with *E. histolytica*. A recent study in baboons tested a Gal-lectin peptide vaccine containing amino acids 758–1134 of the heavy subunit with cholera toxin adjuvant [68]. Repeated intranasal immunizations in uninfected seronegative baboons, induced antigen-specific serum IgA and IgG as well as intestinal IgA antibodies capable of neutralizing amebic activity *in vitro*. Continued research in this area is crucial to the advancement of vaccine development for amebiasis.

The strategy for a protective vaccine against amebiasis is to formulate a vaccine that will be administered orally to stimulate gut mucosal immunity. Oral vaccines are easy to administer and with the right formulation could stimulate both mucosal and systemic responses. Recently, efforts have been made to address the feasibility of an oral amebiasis vaccine. The advent of genetic engineering has led to the development of transgenic

plants capable of expressing vaccine antigens without the common contaminants found in bacterial or yeast expression systems. The Gal-lectin heavy subunit gene was inserted into the chloroplast genome of the tobacco plant to evaluate its potential use as an oral vaccine [69]. The plants expressed the Gal-lectin protein, and crude plant extracts were able to induce Gal-lectin-specific antibodies when administered subcutaneously. Although the plants were not ingested in this study, it was the first report of Gal-lectin expression in a plant system that could facilitate oral vaccine delivery. Another recent study examined the use of live attenuated *Yersinia* to deliver the Gal-lectin protein to the gut mucosa [63]. *Yersinia* can colonize the Peyer's patches, and through its type III secretion system present the vaccine antigen to lamina propria immune cells. Using *Yersinia* as a delivery system protected gerbils from amebic liver abscess formation and was associated with an elevated IFN-γ production. Other studies have also tested the use of attenuated *Salmonella* strains containing plasmids encoding amebic proteins. These studies have established the feasibility of using various expression systems to deliver *E. histolytica* antigens to the gut associated lymphoid tissues (GALT).

Finally, perhaps the most important factor in developing an amebiasis vaccine is to continue to investigate the natural immunity mechanisms in the human population as well as to find innovative ways to mimic that immunity in a vaccine. Epidemiological studies and experimental vaccine studies are powerful tools that are helping elucidate the path to an effective vaccine.

# TOXICOLOGY

John H. Duffus
*Edinburgh Centre for Toxicology, Edinburgh, Scotland, United Kingdom*

## 1 INTRODUCTION

Toxicology is most simply defined as the science of poisons. Using naturally occurring substances—first as foodstuffs and subsequently as drugs—must inevitably have led to the recognition of poisoning as a result of excessive intake or overdose at a very early stage in human evolution. There must also have been recognition that death or other ill effect sometimes followed the intake of very small amounts of a foodstuff or other substance. This would have led to the deliberate use of such substances as poisons and their use on weapons, such as arrows, to paralyze or kill. The use on arrows led to the science of toxicology, derived from the Greek word τοξικον (toxicon) for an arrow poison. Today, the main emphasis of toxicology is on detecting and preventing the unwanted effects of chemical agents, although their use as poisons, especially as pesticides and in chemical warfare, continues.

Toxicology is not a "pure science." It occupies an interface between chemistry, medicine, and biology and is embedded in legislation that governs what substances may be manufactured and how they are used. Thus, it influences, and is itself influenced by, laws and regulations introduced to protect people from the toxic effects of substances that, like pharmaceuticals, may have been marketed because of their beneficial effects when used properly. As a result, the findings of toxicology can have profound economic effects and whole industries, such as asbestos manufacturing, may collapse if their products are condemned as excessively toxic in normal use.

The main objective of toxicology is to prevent harmful effects of useful substances, including therapeutic agents. For new pharmaceutical agents, extensive toxicity and efficacy data are required, including data from volunteer studies in humans. Pharmaceutical agents, at appropriate dose levels, are expected to have a beneficial effect on patients. Other substances, in normal use, whatever their beneficial effects, should have no biological effects on people. This includes pesticides, which, when used as intended, should produce a biological effect in pests without any effect on humans. Absence of effect of pesticides on people depends partly on differences in biochemistry and physiology between pests and humans and partly on careful application of the pesticides to minimize human exposure.

This chapter on toxicology can give you only a limited idea of all that is involved on the subject and you are strongly advised to refer to one or more of the good general textbooks that are available [1–3].

## 2 BASIC PRINCIPLES

Three concepts underlie modern toxicology. The most fundamental may be paraphrased as "the dose makes the cure or the poison." This concept was first recorded by Paracelsus (Theophrastus Phillippus Aureolus Bombastus von Hohenheim, 1493–1541), a Swiss physician and alchemist. In other words, all substances, including pharmaceuticals, are potentially toxic. Defining precisely the therapeutic dose and the toxic dose is, thus,

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad
Copyright © 2010 John Wiley & Sons, Inc.

essential if pharmaceuticals are to be used successfully in treating disease. For other substances, regulation must ensure that "safe" exposure levels are not exceeded. Determining safe exposure levels is thus a major activity of regulatory toxicologists. This requires establishing a permissible exposure level (PEL) for all substances that may reasonably be considered to pose a risk to humans or other organisms of concern.

The second essential concept is that the biological effects of different substances depend upon their chemical structure. This concept has been associated with Ambroise Paré, a sixteenth-century French surgeon who recognized that toxic agents have different effects depending on their inherent character. Studying the relationship of chemical structure to biological effect (structure–activity relationship, SAR) is a central activity of both pharmacology and toxicology and has been of great importance in the development of more effective and safer drugs and pesticides.

The third essential concept is that humans are mammals and thus effects on other mammals are likely to apply also to humans. This concept has enabled toxicologists to derive an understanding of the nature of toxicity and the mechanisms that produce it by extrapolating from experimental studies of effects on other mammals such as rats and mice exposed to substances of concern. Because mammalian species are not identical, such extrapolations are done with care to allow for known differences in physiology and metabolism. As our understanding of toxicity to mammals, and especially to humans, has developed, it has been possible to improve our protection of humans from toxicity and to provide effective treatment of poisoning when it occurs.

## 3 DOSE–EFFECT AND DOSE–RESPONSE RELATIONSHIPS

There are two types of dose–effect relationships. One has a threshold below which no effect occurs (Fig. 1). Although it is almost impossible to determine a threshold value precisely by experiment, doses just above or just below the threshold can be measured and used as approximations for the calculation of safe exposure levels. This will be described below.

A threshold can be identified for all toxic effects except for mutagenic effects, including those that lead to the subsequent development of cancer, and for some, if not all, teratogenic effects. A mutation can theoretically occur through a single chemical molecule producing a change in the chemical structure of a single DNA (Deoxyribonucleic acid) molecule, altering the nucleotide sequence and its transcription product. Two molecules have twice as much chance as causing this effect and so on. This leads to a linear relationship between the dose of a mutagenic substance and the probability that a mutation will occur (Fig. 2). The true risk of a single molecule causing a mutation is infinitely small and there are also many defense mechanisms within cells, including DNA repair mechanisms, which can prevent mutation from occurring. Thus, it is very likely that thresholds exist even for mutagenic effects, but so far no test method exists to establish such thresholds, and thus determination of permissible exposure levels for such effects must be based on calculations of their probability. It is generally agreed that a significant risk is reached with a high enough exposure to produce a

**Figure 1** Dose–effect relationship for a nonnutrient substance with a threshold dose below which no effect occurs (a nonstochastic relationhip).

**Figure 2** Dose–effect relationship for a nonnutrient carcinogenic substance assuming there is no threshold dose. Thus increasing the dose is associated with increasing probability of a toxic effect occurring (a stochastic relationship). MTD = maximum tolerated dose—the highest *dose* that is expected on the basis of an adequate *subchronic* study to produce only limited *toxicity* when administered for the duration of the test period.

probable excess incidence of disease of above one in a million in the exposed population.

## 4 CHEMICAL INTERACTIONS

A major problem in assessing the likely effect of exposure to a chemical is that of assessing possible interactions [4]. The simplest interaction is an additive effect: This is an effect that is the result of two or more chemicals acting together, which is the simple sum of their effects when acting independently. In mathematical terms: $1 + 1 = 2$, $1 + 5 = 6$, and so on. The effects of organochlorine pesticides are usually additive reflecting similar structures and mode of action.

More complex is a synergistic (multiplicative) effect: This is an effect of two chemicals acting together that is greater than the simple sum of their effects when acting alone; it may be called synergism. In mathematical terms: $1 + 1 = 4$, $1 + 5 = 10$, and so on. Asbestos fibers and cigarette smoking act together to increase the risk of lung cancer by a factor of 40, taking it well beyond the risk associated with independent exposure to either of these agents.

Another possible form of interaction is potentiation. In potentiation, a substance that on its own causes no harm makes the effects of another chemical much worse. This may be considered to be a form of synergism. In mathematical terms: $0 + 1 = 5$, $0 + 5 = 20$, and so on. For example, isopropanol, at concentrations that are not themselves harmful to the liver, increases (potentiates) the liver damage caused by a given concentration of carbon tetrachloride.

The opposite of synergism is antagonism: An antagonistic effect is the result of a chemical counteracting the adverse effect of another; in other words, the situation where exposure to two chemicals together has less effect than the simple sum of their independent effects. Such chemicals are said to show antagonism. In mathematical terms: $1 + 1 = 0$, $1 + 5 = 2$, and so on. An example of this is the antagonism of compounds containing SeH groups for compounds containing reactive mercury species.

While we recognize that such interactions occur, we are still at a very early stage in our ability to predict when they are likely. It may be that a number of the adverse reactions that have been attributed to specific drugs are, in fact, the results of their interactions with other drugs, or environmental chemicals, or even with substances that are otherwise nutrients. Probably the drug interaction with adverse effects that has the most recognition is that with alcoholic drinks, which potentiate the toxic effects of a number of drugs.

## 5 SAFETY ASSESSMENT

Safety assessment is the name given to the process that results in establishing for humans an "acceptable daily intake" (ADI) for specific chemicals or a "therapeutic dose" for pharmaceuticals. Safety assessment is normally based on data from mammalian toxicity tests made with the underlying assumption that humans are sufficiently similar to the mammals used in tests to permit extrapolation of observed effects and dose–effect and dose–response relationships. However, it is also recognized that humans may be more sensitive than the most sensitive mammalian species tested and calculation of safe exposure levels makes allowance for this [5].

## 6 CLASSIFICATION AND LABELING

In practical terms, the first step in safety assessment for the user of any substance is to look at the information given on the label of the chemical container. Many countries have now passed laws or regulations that legally require specific toxicity information to be given on labels or on safety data sheets (SDS), allowing appropriate protective measures to be taken. However, these laws and regulations vary, and this can cause confusion, particularly when a chemical has wide international usage. Thus, a Global Harmonization System (GHS) has been developed and is expected to be finally agreed upon soon [6].

The toxicity information is derived from data from appropriate tests that are discussed further below. For information on how toxicity data are interpreted in the GHS for the purposes of labeling, see the document prepared by the Environmental Protection Agency U.S. (EPA) Office of Pesticide Programs [7].

## 7 TOXICITY TESTING

Safety assessment depends mostly upon in vivo testing programs using mammals, usually rats and mice, although teratogenicity tests must also be carried out on nonrodents such as rabbits. This follows the failure to detect the teratogenic effect of thalidomide in rodents and the resulting phocomelia that occurred in the children of women who had been treated with this drug.

In vivo tests must be carried out in at least two mammalian species and may be for short periods or for a complete lifetime, depending upon the actual or suspected adverse effects. For example, a suspected human carcinogen may require lifetime exposure of a rodent (2

years in the rat) before malignancy can be detected. Lifetime tests are very expensive, and often a suspected carcinogen will be banned from use without such tests unless it has a unique and important use for which no substitute is readily available.

All toxicity tests providing data for regulatory purposes must conform to Good Laboratory Practice (GLP) guidelines. These guidelines originate with the Organization for Economic Cooperation and Development (OECD) [8]. GLP requires that all staff involved must be appropriately trained, follow standard operating practice (SOP), keep meticulous records, and archive all records and samples that contribute significantly to the data. The need for GLP guidelines is an acknowledgment of the serious consequences that may follow toxicity classification, whether low, permitting marketing and use of a substance, or high, preventing marketing and use.

## 8 SHORT-TERM (ACUTE) TESTS

Short-term (acute) tests are conducted in both sexes of one or more rodent species with the purpose of determining the dose range for adverse effects of a substance and to determine the exact shape of the dose–response curve. In addition to the determination of the no-observed-adverse-effect level (NOAEL), the benchmark dose (BMD), the $LD_{50}$ (the median dose lethal to half the test organisms), and/or the lowest-observed-adverse-effect level (LOAEL), or the limit dose (a legally defined no-effect dose used for toxicity classification), the results of acute studies may be used to establish the appropriate dose range for longer-term experiments. At the end of a study all animals are autopsied, with complete gross and microscopic examination of tissues. Blood chemistry is evaluated and an overall clinical assessment is made on each animal.

As well as establishing dose dependency of effects, acute studies can determine the nature of toxicity, time of onset of toxic signs, and the capacity for recovery in the surviving animals. This information is essential in any emergency situation where humans or domestic animals have suffered from poisoning. Acute toxicity studies may also help in identifying antidotes to a given toxicant.

## 9 MEDIUM-TERM (SUBCHRONIC) TESTS

Subchronic tests are generally conducted in both sexes of two mammalian species, one of which is a nonrodent species, often the rabbit. Such studies generally last 3–6 months, covering a range of doses. The main aims of a subchronic study are to determine target-organ toxicity, to determine the effects of prolonged dosing, and to provide more evidence on which to base regulation of exposure levels for food additives and drugs. As with acute tests, at the end of a study all animals are autopsied, with complete gross and microscopic examination of tissues, evaluation of blood chemistry, and a complete clinical assessment of each animal.

## 10 LONG-TERM (CHRONIC) TESTS

If the safety of use of a potentially valuable substance is still unclear after subchronic tests, chronic tests may be required. Such studies are carried out for a time that approaches the life span of the animal. Again they are applied to at least two mammalian species, usually a rodent and a nonrodent, and in both sexes. Chronic studies need careful management with multiple clinical evaluations, daily observations, weekly food and water consumption records, and body weight determinations. At the end of the study, on death, and (or) at intermediate times, if thought necessary, all animals are autopsied.

Chronic toxicity studies provide the most complete information on the effects of a given substance on homeostasis, bodily functions, induced diseases, and total life span. For drugs, they provide the most valuable preclinical information for assessment of safety and risk.

Where there is a potential for a substance to cause cancer, a specific cancer bioassay may be required. Such a bioassay is conducted in rats and mice and lasts for the natural life span of the species. The test is usually carried out at two dose levels, the maximum tolerated dose (MTD) and the half maximum tolerated dose, preferably mimicking the route of human exposure. Sometimes nonphysiological routes of exposure, such as intraperitoneal injection or intramuscular injection, have been used but the data from these must be viewed with some scepticism. In particular, the process of intramuscular injection may trigger neoplasia even with otherwise relatively harmless substances.

The possibility of reproductive toxicity must be tested in several species because there is no species that provides a perfect model to predict possible effects in humans. Rats, mice, rabbits, and sometimes dogs may be used for tests. The main objective is to find out whether the test substance alters the reproductive cycle of the female or spermatogenesis in the male. However, the tests are also designed to examine the effects of the given substance during the first, second, and third trimester of pregnancy and during parturition and lactation. Multigenerational studies are conducted to determine the overall effects of a given chemical on the

parent generation, the offspring, and on the ability of the offspring to reproduce normally.

## 11 SCREENING FOR MUTAGENICITY AND POSSIBLE CARCINOGENICITY—THE AMES TEST

The Ames test is named after its creator, Dr. Bruce Ames. The test is one of a number [9, 10] used as a screening test to identify mutagens and hence for mutagenic carcinogens. It is universally required in any battery of tests for potential toxicity. It is, therefore, important to understand it so that its results are properly interpreted.

The test uses strains of *Salmonella typhimurium* that have been altered by genetic engineering to make them unable to synthesize histidine. They are, therefore, dependent on an exogenous supply of this amino acid unless a mutation restores the histidine biosynthesis pathway. They are also engineered to be much more susceptible to mutation than the normal bacterium as a result of loss of DNA repair systems. Mutations occur when the bacterial DNA is altered by interaction with the test substance or with a reactive metabolite produced from the test substance.

To perform the test, selected *Salmonella* strains are mixed in a test tube with a solution of the substance of interest. Because the bacteria lack the cytochrome P450 enzymes that metabolize many foreign chemicals in mammals, rat liver enzymes (the so-called S9 microsome preparation) are added to the test system in a second test tube to permit metabolic products to be assessed. After exposure, the bacteria are transferred to histidine-deficient nutrient agar in a Petri dish for one or two days to see if they can grow. Without mutation, the bacteria used for the test require the amino acid histidine to grow. Thus, only mutated bacteria that have recovered the ability to synthesize histidine can grow on the histidine-deficient agar, and the number of colonies is a measure of the mutagenic potency of the substance tested.

A positive result in an Ames test does not prove that a particular chemical is a mutagen for normal cells nor that it is capable of causing cancer. Essentially, the Ames test simply shows a capacity to alter DNA in cells that are extremely sensitive to DNA damage. Thus, a number of chemicals that test positive in the Ames test do not cause mutations in mammalian cells or subsequent cancer. Further, some chemicals that are known to cause cancer do not test positive in the Ames test. More extensive testing is, therefore, needed to determine whether a chemical is truly carcinogenic in humans. The test is useful as a screening tool because it is inexpensive and quick. It is used to eliminate potential mutagens and carcinogens early in the process of developing new drugs and other substances.

## 12 OTHER IN VITRO TESTS

Other in vitro tests have been developed to assess potential immunotoxicity, hormone action, eye irritation, and other changes that are correlated with disease. However, only a few of these have been validated. The advantages of in vitro tests are that they are quick, relatively inexpensive, and that specific mechanisms of action can be tested. The major disadvantage of these tests is that the homeostatic mechanisms, repair pathways, and hormonal regulatory systems found in mammals are not present. This makes it very difficult to extrapolate the data from most of these tests to assess risk to the human species.

## 13 TIERED TOXICITY TESTING

The strategy now used for toxicity evaluation of substances is described as a tiered strategy. The first tier includes in vitro and acute studies. From this, further tiers proceed to a final tier of multigenerational studies and carcinogenesis bioassays. Special tests may be needed for special toxicity problems, for example, endocrine disruption or modification, now a matter of great concern.

## 14 ESTABLISHING SAFE EXPOSURE LEVELS

### 14.1 For Occupational Health and Safety [11]

Safety factors, better called uncertainty factors, are used in establishing public health and regulatory guidelines and standards based on the available toxicological data. For substances producing toxic effects with a threshold dose, the regulatory values are usually based on surrogate values for the threshold. These values may be the NOAEL, the BMD, the LOAEL, the limit dose, or, in the absence of any better datum, the $LD_{50}$ (the median dose lethal to half the test organisms). The surrogate value is reduced by dividing it by an uncertainty factor of 10 to allow for the differences between mammals and humans and the possibility that humans are more sensitive. Another 10-fold factor is applied to allow for extremely sensitive groups that may occur in the human population. The resultant 100-fold ($10 \times 10$) safety level is the minimum normally used for establishing regulatory standards. An additional uncertainty factor of 10 may be applied where there is reason to suspect that the available data are poor or where there may be special sensitivity considerations, thus dividing the

surrogate value by 1000 (10 × 10 × 10) in order to derive a permissible exposure level. Ultimately, scientific judgment must be applied in the use of uncertainty factors and robust data from epidemiological studies on humans may permit a minimum uncertainty factor of 10 to be applied in a very small number of cases.

### 14.2 For Food Additives

Safety assessment for food additives, such as colorants or flavors, is normally calculated as an acceptable daily intake (ADI) for the relevant foodstuff containing the additive [12]. As usual, the calculation is based on the NOAEL (or other threshold surrogate) in laboratory mammals, with the application of appropriate uncertainty factors. The ADI is defined as an estimate by the World Health Organization (WHO) Joint Expert Committee on Food Additives (JECFA) of the amount of a food additive, expressed on a body weight basis, that can be ingested daily over a lifetime without appreciable health risk. For the calculation of the ADI, a standard body mass of 60 kg is assumed. Tolerable daily intake (TDI) is the analogous term used for contaminants.

### 14.3 For Therapeutic Agents

Safety assessment for therapeutic agents is also based on mammalian toxicity data and is a function of the dose to be prescribed, the diseases to be treated, and the nature of the population at risk [13, 14]. The safety assessment for an over-the-counter (OTC) drug is more stringent than for a drug to be used for the treatment of a life-threatening situation.

A therapeutic index (TI) can be developed for most drugs. The TI is the ratio of the toxic dose to the therapeutically effective dose. The greater TI, the greater is the margin of safety in use of the drug. A drug used for cancer chemotherapy may have a greater toxicity and a much smaller TI than a drug used to treat the common cold. A cancer patient is in a life-threatening situation and during treatment is constantly monitored by a doctor or nurse for signs and symptoms of toxicity. Thus, the drug treatment can be suspended quickly if the toxic effects become a problem. The situation is different for a person taking uncontrolled amounts of an OTC product. Such a person is not subject to regular monitoring by a health professional. Furthermore, there is a very large consumer population for OTC products and a significant part of this population is unaware of the risks of toxicity associated with these products.

### 14.4 For Household Products

Household products present particularly difficult problems for toxicity assessment and regulation. Anything can happen to such products, and it is possible that the consumer may be exposed to them by any route. Because of this, packaging and labeling must be considered as part of the safety assessment and regulation. Thus, a household cleanser that is caustic and highly oxidizing must be given strong, vivid, unequivocal labeling and childproof packaging.

## 15 TOXICOKINETICS

Whatever tests are done, there is always the possibility of failing to identify a potentially toxic substance. This possibility may be reduced if the way in which the mammalian body handles the substance is known. The physiological handling of substances by the body is usually considered in terms of absorption, distribution, metabolism, and excretion, the relevant science being described by the term toxicokinetics.

Absorption, the process that links chemical exposure to internal dose, normally occurs by ingestion, inhalation, or through the skin, although therapeutically it may involve intravenous, intramuscular, or other forms of injection or implantation into the body. Processes of distribution, metabolism, and excretion vary depending upon the route of absorption. Toxicokinetic consequences then depend upon the site of injection or implantation and must be assessed specifically for each case. Rectal or vaginal suppositories require special consideration.

Distribution from the site of absorption may involve both blood circulation and lymphatic circulation. Metabolism of the absorbed substance may occur at any stage of distribution and in any cell, tissue, or organ. The liver is a major metabolic organ, and it is particularly important for substances absorbed from the small intestine following ingestion. Some substances, such as benzene, are harmless until they are metabolized by the body to form toxic derivatives. Other substances pass through the body unchanged, while others react directly with receptor molecules.

The chief excretory pathways are urination, defecation, and exhalation. Lactation is also a means of excretion, particularly of fat-soluble chemicals, to the potential detriment of the infant. Under hot conditions, sweating may be more important than urination for the excretion of water-soluble substances. Under these circumstances, volatiles may be lost to the air while some substances may be reabsorbed through the skin. Some substances such as mercury or inorganic arsenicals may be excreted in hair and nails. A minor but important route of excretion is into genital secretions. Substances excreted by this route may adversely affect fertility.

Sensitivity to toxicity varies from person to person, depending on factors such as genetics, age, sex, and environmental conditions. It is generally thought that children, the elderly, and those with pre-existing disease may be more susceptible to toxicity than healthy adults but this may not always be true.

## 16 INTERACTION OF GENES AND TOXICITY [15]

Genes act by programming nucleic acids and proteins that support the formation of a molecular system in cells and organisms, including people, upon which environmental factors act. Among these environmental factors are chemicals, drugs, and infectious agents in air, water, food, and consumer products. The environmental factors are in addition to other physical and psychosocial stresses, and all these stresses may interfere with normal cellular functioning of the system and cause disease. For example, polycyclic aromatic hydrocarbons are produced by combustion of oil, coal, cigarettes, and various industrial processes; these chemicals are breathed in through the lungs, enter the circulating blood, and are converted in the liver and other organs into highly reactive intermediates that form chemical adducts with any DNA they contact. Adducts cause the DNA genetic code to be misread, leading to mutations that may be harmful in themselves and may ultimately cause cancers.

Many pharmaceutical agents have variable therapeutic effects and toxic effects in different patients. Drugs may be metabolized (changed by enzyme action) into more active, or less active, molecules, depending on the inherited form of the gene coding for a relevant enzyme. The same applies to nutrients. Discovery of this gave rise to the concept of "inborn errors of metabolism," a phrase introduced by Sir Archibald Garrod in 1908. It was discovered in the case of the amino acid phenylalanine that specific mutations, usually involving both the maternal and the paternal forms of the gene (an autosomal recessive pattern of inheritance, with 25% risk for each offspring), caused deficiency of a key enzyme necessary for its metabolism. Because of this, in those with recessive genes from both parents, phenylalanine became toxic to the developing brain at the doses obtained from a normal diet. The effects of the resultant disorder (phenylketonuria, or PKU) can be prevented by diagnosing the condition at birth through newborn screening of a heel-stick blood sample and putting the child on a diet low in phenylalanine for the first 5 years of life, while the brain is growing rapidly. The special diet can be less stringent during childhood and adolescence. For women, it is crucial that they are put on a stringent low-phenylalanine diet during pregnancy; otherwise, the high circulating levels will damage the fetus with a 100% risk of mental retardation.

A classic genetic disorder affecting tissue response to xenobiotics is glucose-6-phosphate dehydrogenase (G6PD) deficiency. G6PD is the first rate-limiting enzyme in the pentose phosphate shunt pathway, essential to maintenance of the integrity of the red blood cell membrane. Mutant types of G6PD associated with enzyme deficiency are found at significant frequencies in black and Mediterranean populations. Since the gene for G6PD is carried on the X chromosome, males are most likely to be affected. Many drugs with oxidizing properties can cause acute hemolysis in otherwise healthy but genetically predisposed people by overwhelming the capacity of G6PD-deficient red blood cells to counteract oxidative stress. Such stress may also be caused by exposure to a component of fava beans, the pyrimidine aglycone divicine, or to naphthoquinone in mothballs. Hepatitis and diabetic acidosis are also associated with red blood cell damage resulting from G6PD deficiency.

Other examples of well-established examples of genetic disorders affecting drug metabolism are:

1. Deficiency in succinylcholinesterase activity: Succinylcholine causes prolonged and life-threatening paralysis of respiratory muscles in the 1 in every 2000 people who inherit two copies of the recessive gene for an atypical form of the enzyme, plasma pseudocholinesterase; otherwise, such people are entirely normal.
2. Deficiency in acetylation: A recessive mutation in hepatic *N*-acetyltransferase reduces the activity of this important acetylating enzyme; slow acetylators are liable to side effects from hydralazine, isoniazid, dapsone, and some sulfa drugs; about 50–55% of Caucasian and black populations are slow acetylators, whereas only 10–15% of Orientals are slow acetylators. According to Calabrese [15], the hypothesis that slow acetylators are at increased risk of arylamine-induced bladder cancer has good theoretical foundations in animal model studies; epidemiological evidence is consistent with the animal data.
3. The 4% of the general population who are carriers of the serum alpha-antitrypsin (SAT) deficiency are at enhanced risk (2 times normal) of developing pollutant-induced emphysema.

More knowledge is needed about the heterogeneity of genetic predispositions, environmental exposures, and disease risks. Unfortunately, most public health research on infectious disease and environmental chemical risks has paid little attention to inherited

susceptibility in people, focusing only on the environmental disease agents. Heterogeneity of study populations has often been neglected in epidemiological studies in order to generate sufficient numbers to justify the analysis statistically. For quantitative traits, pharmacologists, toxicologists, and psychologists have generally emphasized means and standard errors of the means, and neglected potentially informative people with values outside two standard deviations from the mean.

Nutrition and genetics interact extensively. A fairly common genetic disorder, hereditary hemochromatosis, results in sensitivity to iron in the diet at relatively low amounts, leading to damage from iron deposition in the heart, liver, pancreas (diabetes), testes (infertility), skin, and joints (arthritis).

## 17 ECOTOXICOLOGY [16]

For some time, there has been a requirement in many countries for premanufacturing notification of new chemicals and their properties, including their toxicity, both to humans and to other organisms that may be at risk. Recognition of the dangers inherent in compounds, and especially those that bioaccumulate or otherwise persist in the environment, has led to further tests to identify and to exclude from commerce such compounds, including pharmaceuticals since they are designed to be biologically active and must ultimately reach the natural environment in some form. This requires making due allowance for the chemical transformations that occur in treated humans and animals and under environmental conditions.

Toxic effects of substances on ecosystems may have an adverse effect on human health. Historically, ecotoxicology (in relation to human health) has concentrated on contamination of the food chain, especially the bioaccumulation of toxic agents in food. Now there is an understanding that there are effects of substances on climate, desertification, and crop yield, all of which impact upon human health. The natural world contributes enormously to human well-being, and an appreciation of this has led to a body of legislation designed to prevent or minimize further environmental degradation.

## 18 ECOSYSTEMS

The health of humans, like that of all living organisms, is dependent on living in a healthy ecosystem. Ecosystem degradation can lead to human health risks from unsafe drinking water, polluted air, climate change, emerging new diseases, and the resurgence of old diseases resulting from ecological imbalances.

An ecosystem may be defined as a community of plants and animals interacting with each other and with their environment. Ecosystems may be differentiated on the basis of the dominant vegetation, the topography, the climate, or other criteria. For example, prairies are characterized by the predominance of grasses. The Arctic tundra is determined partly by its harsh climatic zone. In most parts of the world, the human community is the dominant component of the ecosystem. Ecosystems include not only natural areas (e.g., forests, lakes, or marine coastal systems) but also manmade systems (e.g., urban ecosystems, agro-ecosystems, or impoundments). Human populations are increasingly concentrated in urban ecosystems, and it is estimated that already 50% of the world's population is living in urban areas.

Any given area comprises a mosaic of ecosystems and includes towns, rivers, lakes, agricultural systems, and so on. Precise boundaries between ecosystems are often difficult to establish. Regions may overlap gradually, with a fairly wide "transition" zone.

## 19 ECOSYSTEM HEALTH AND TOXICITY

*Ecosystem health* is a term that is difficult to define precisely. It is easier to define examples of ecosystems that have become "sick," particularly as a result of human activity. For example, the discharge of nutrients from sewage, industrial waste, or agricultural runoff into lakes or rivers adversely affects the normal functioning of their ecosystems. This is an example of ecosystem toxicity. Excessive nutrient inputs from human activity caused considerable ecological damage to Lake Erie, Lake Ontario, and Lake Michigan. This effect, called *eutrophication* has affected many natural waters around the world.

Resilience is the capacity of an ecosystem to maintain its structure and functions in the face of disturbances. Systems that have been pushed by environmental stresses to the extreme limits of their resilience are less likely to recover from further stress of human pollutants than are those systems that have been relatively less stressed.

Healthy ecosystems can be characterized in economic, social, and human health terms. Healthy ecosystems can support a certain level of human economic activity. This potential should always be given due consideration before decisions on further development are made. If human developments exceed their environmental sustainability, ecosystem degradation will ensue and undermine the long-term sustainability of the human economy that is associated with it. In the short

term, ecological damage may not be evident, as natural capital (e.g., soils and otherwise renewable resources) may tolerate overuse temporarily and permit enhanced economic returns.

## 20 ECOSYSTEM PATHOLOGY

Human activities paralleling human population increases are now the main cause of healthy ecosystems becoming sick. Natural disturbances (fires, floods, drought, periodic insect infestations, or infectious disease) are built in to the dynamics of most ecosystems. These processes help to "reset" ecosystems by recycling nutrients and clearing space for recolonization by biota that may be better adapted to changing environments. On the other hand, stresses imposed on ecosystems as a result of human activity, such as the release of nutrients and toxic substances into the air, water, and land, often result in chronic ecological dysfunction.

Waste chemical discharges from municipal, industrial, and agricultural sources into air, water, and land have severely damaged many of the Earth's ecosystems. The effects are particularly apparent in aquatic ecosystems, for example, the effects of atmospheric acid precipitation or other acidic discharges. In some lakes that lack a natural buffering capacity, acid precipitation has eliminated most of the fish and other organisms as a result of the pH of the water being lowered to a level that made aluminum ions available in solution at a toxic concentration. Systems that once contained a variety of organisms and were highly biologically productive have become devoid of most life-forms except for a few acid-tolerant bacteria and sediment-dwelling organisms.

## 21 ECOSYSTEM HEALTH AND HUMAN HEALTH

An important aspect of ecosystem degradation is the associated increased risk to human health. Traditionally, the concern has been with contaminants, particularly industrial chemicals that can have adverse impacts on human development, neurological functions, reproductive functions, and that appear to be causative agents in a variety of carcinomas. In addition to these environmental concerns (where the remedy is often reduction in the release of contaminants), there are a large number of other risks to human health stemming from ecological imbalance.

Ecosystem pathology results in the loss of valued ecosystem services, including flood control, water quality, air quality, fish and wildlife diversity, and recreation. One of the major signs of ecosystem pathology is increased disease incidence, both in humans and other species. Human population health can thus be viewed in an ecological context as an expression of the integrity and health of the life-supporting capacity of the environment.

Ecological imbalances triggered by global climate change, itself believed to be a product of human action releasing "greenhouse gases" into the atmosphere, lead to increased human health risks. Global climate change, particularly as it impacts both temperatures and precipitation, is highly correlated with the prevalence of vector-borne diseases.

The increase in prevalence of *Vibrio cholerae* has been strongly linked to degraded coastal marine environments [17]. Nutrient-enriched warmer coastal waters, resulting from a combination of climate change and the use of fertilizers, provide an ideal environment for reproduction and dissemination of *V. cholerae*. Nutrient enrichment and warmer temperatures give rise to algal blooms and an abundance of macrophytes. The algal blooms provide abundant food for copepods, and the increasing copepod and macrophyte populations provide *V. cholerae* with a habitat. Subsequent dispersal of *V. cholerae* into estuaries and freshwater bodies allows contact with humans who use these waters for drinking and bathing. Global distribution of marine pathogens such as *V. cholerae* is further facilitated by ballast water discharge from vessels. Ballast water is transported from its source over long distances to the discharge point and may contain a cocktail of pathogens, including *V. cholerae*.

## 22 ANTIBIOTIC RESISTANCE AND AGRICULTURAL PRACTICE

Antibiotic resistance is a growing threat to public health [18]. Antibiotic resistant strains of *Streptococcus pneumoniae*, a common bacterial pathogen in humans and a leading cause of many infections, including chronic bronchitis, pneumonia, and meningitis, have greatly increased in prevalence since the mid-1970s. In some regions of the world, up to 70% of bacterial isolates taken from patients proved resistant to penicillin and other β-lactam antibiotics. The use of large quantities of antibiotics in agriculture and aquaculture appears to have been a key factor in the development of antibiotic resistance by farm animal pathogens that may subsequently infect humans. One of the most serious risks to human health from such practices is vancomycin-resistant enterococci. The use of avoparcin, an animal growth promoter, appears to have compromised the utility of vancomycin, the last antibiotic effective against multi-drug-resistant bacteria. In areas where avoparcin

has been used, such as on farms in Denmark and Germany, vancomycin-resistant bacteria have been detected in meat sold in supermarkets. Avoparcin was subsequently banned by the European Union. Another example is the use of ofloxacin to protect chickens from infection and thereby enhance their growth. This drug is closely related to ciprofloxacin, which was one of the most widely used antibiotics in the year 2000. There have been cases of resistance to ciprofloxacin directly related to its veterinary use. In the United Kingdom, ciprofloxacin resistance developed in strains of *Campylobacter*, a common cause of diarrhea. Multidrug-resistant strains of *Salmonella* have been detected in European egg production facilities.

## 23 ECOSYSTEM RESTORATION

Ecosystem pathology can be reversed in some cases simply by removing the source of stress. In cases, for example, where ecosystem degradation is the result of point-source additions of nutrients or toxic chemicals, removal of these stresses may result in recovery of ecosystem health. A classic case is Lake Washington (near Seattle, Washington) [19]. This lake had become highly anoxic (oxygen depleted) owing to a sewage outfall entering the lake. Redirecting the sewage outfall away from the lake reversed many of the signs of ecopathology.

In cases where it is not feasible to remove the source of stress, it may be possible to minimize the stress. For example, in the Kyrönjoki and Lestijoki Rivers in western Finland, spring and autumn runoff leads to sharp pulses of acidity because of release of acid from tilled or dug soils. This runoff has been particularly damaging to fish during the critical time of year for spawning. Fish reproduction is severely curtailed, if not all together eliminated in highly acidic water. There have also been massive fish kills resulting from the highly acidic waters. Replacement of the original drains that take runoff to the rivers with new drains containing lime to neutralize the acidity appears to provide at least a partial solution to the problem [20].

## 24 PREVENTION OF ECOSYSTEM DAMAGE

Because it is very difficult to reverse ecosystem degradation, and because of the many human health problems associated with the loss of ecosystem health, it is clear that every effort must be made to prevent ecosystem disruption. In both developed and developing countries there is strong pressure for economic growth in spite of accompanying environmental damage. The justification for this is that economic growth has many obvious health benefits, such as providing more plentiful food, and funding for better health services as well as supporting research to improve standards of living.

However, the human population is at an all-time high, and the associated human activities have led to more and more degradation of the Earth's ecosystems. In this respect, there is growing concern about the contamination of the environment by therapeutic agents and their derivatives as components of human waste. These substances have been detected in rivers and associated with effects on wildlife, including feminization of male fish by hormonal therapeutics and their excretory products. Thus, a new area of toxicology is developing as more and more regulators require assessment of possible environmental effects of human and veterinary therapeutics at all stages from production to final disposal by whatever means.

# DEVELOPMENT OF PHOSPHODIESTERASE 4 INHIBITORS FOR ALLERGIC AND NONALLERGIC INFLAMMATORY DISEASES OF THE AIRWAYS

Mark A. Giembycz

*Department of Physiology & Pharmacology Institute of Infection, Immunity and Inflammation, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada*

## 1 INTRODUCTION

Asthma and chronic obstructive pulmonary disease (COPD) are the most common respiratory disorders and together, in the global population, currently afflict >1.5 billion individuals. The prevalence of asthma is rising worldwide, and this has become the most common chronic disease in industrialized nations with 5–10% of the population being affected [1]. For example, in the United States, asthma attacks are a primary cause of hospitalization—497,000 discharges due to asthma were recorded in 2004—and, in the preceding year, were responsible for 4099 deaths [2] (see www.lungusa.org). Asthma is a chronic inflammatory disease characterized by *reversible* airway obstruction, airway remodeling, and nonspecific airway hyperresponsiveness (AHR) [3, 4]. The inflammation in asthma is multifaceted, often allergic and involves both infiltrating leukocytes and structural cells. $CD4^+$ T lymphocytes are believed to play a pivotal pathogenic role; they elicit a Th2-driven inflammatory response and, through orchestrating pulmonary eosinophil recruitment, may contribute to airway remodeling, which is a cardinal feature of this disease [5–7].

COPD is a nonspecific term that embraces several debilitating inflammatory pathologies that often coexist and is characterized by a slowly progressive and largely *irreversible* decrement in lung function [8–10]. Persistent chronic airflow limitation, usually associated with airway collapse, edema, mucus hypersecretion, and fibrosis, is present to a greater or lesser extent and accounts for the wide spectrum of the disease [8–10]. COPD afflicts middle-aged and elderly people [11] and is caused, in approximately 95% of all cases, by chronic cigarette smoking, although other environmental insults such as the burning of biomass fuels are also major risk factors [12, 13]. COPD has a long latency before symptoms become evident, afflicts 9–10% of the population globally over the age of 40 years [14], and *is the only cause of mortality that is increasing worldwide* [15]. Indeed, by 2020 the Global Burden of Disease Study predicts that COPD will be the third leading cause of death, driven by the expanding epidemic of cigarette smoking and changing demographics, with more of the global population living longer [16, 17]. Even in 2007, COPD was underrecognized, underdiagnosed, and underreported [18]. Accordingly, COPD is undertreated [13].

A recent systematic review and meta-analysis of studies performed in 28 countries between 1994 and 2004 provides compelling evidence that the prevalence of COPD is appreciably higher in individuals who smoke or who are ex-smokers when compared to subjects who have never smoked [14]. Accordingly, COPD is largely preventable, and, in the early stages, its progression can be arrested by smoking cessation. Unfortunately, the

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*
Edited by Shayne C. Gad

highly addictive properties of nicotine in tobacco render most individuals unable to renounce cigarette smoking despite intensive interventions.

## 2 GLUCOCORTICOIDS AND THE TREATMENT OF ASTHMA AND COPD

Inhaled corticosteroids (ICSs) or, more correctly, glucocorticoids are the most efficacious treatment currently available for asthma (see www.ginasthma.org). These drugs control symptoms, reduce exacerbations, and improve health status in most patients irrespective of disease severity [19]. Accordingly, ICSs are the first-line therapy for all patients who use a $\beta_2$-adrenoceptor agonist inhaler more than once a day, and this is reflected in all national and international guidelines for asthma management (see www.ginasthma.org) [20–23]. In contrast, unlike in individuals with asthma, ICSs appear to be of *relatively* limited benefit in subjects with COPD. Although there is some evidence that certain indices of pulmonary inflammation are suppressed by ICSs (reviewed in ref. 24), the effect on mortality is unclear (see [25]) [26–31]. Currently, there is only one published *prospective* trial of ICSs in COPD that has been powered on mortality and, contrary to *retrospective* analyses [32, 33], that study demonstrated that the rate of death in subjects taking the ICS, fluticasone propionate, alone did not differ from placebo [34]. In contrast, ICSs have unequivocal and clinically meaningful anti-inflammatory efficacy in subjects with asthma and significantly reduce mortality [35].

## 3 PHOSPHODIESTERASE INHIBITORS

Although glucocorticoids can effectively alleviate the inflammation that characterizes asthma, they are not without adverse effects [36, 37]. Accordingly, new drugs with enhanced selectivity and improved side effect profiles are clearly required that also have efficacy in subjects with COPD in whom glucocorticoids are relatively refractory. One group of drugs that, from a theoretical perspective, may exhibit powerful anti-inflammatory and immunomodulatory activity are inhibitors of a large family of enzymes, generically known as cyclic nucleotide phosphodiesterases (PDEs). Eleven structurally and immunologically distinct families have, thus far, been identified that are differentially expressed between different cell types and can also be distinguished from each other in terms of their substrate specificity, dependency on cofactors, and sensitivity to inhibitors (see Table 1 for details) [39–44]. With respect to treating airway inflammatory diseases, it is those enzymes that comprise the PDE4 isoenzyme family—which degrade cyclic adenosine-3′,5′-monophosphate (cAMP)—that are the target for small-molecule inhibitors. The rationale for developing compounds that attenuate PDE4 activity is based on three critical findings: (i) PDE4 is the major regulator of cAMP metabolism in almost every pro-inflammatory and immune cell, and agents the elevate cAMP have a pharmacology consistent with anti-inflammatory activity; (ii) PDE4 inhibitors, of varied structural classes, suppress a myriad of in vitro responses such as cytokine generation, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity, degranulation, proliferation, mediator generation, and chemotaxis; and (iii) PDE4 inhibitors are efficacious in animal models of inflammation [42]. If these observations hold in humans, then, conceptually, PDE4 inhibitors should show a pleiotropic inhibitory profile of activity on pro-inflammatory and immune cell function. Despite the potential for adverse events due to the ubiquitous distribution of PDE4 in "nontarget" cells (see below), almost all of the main pharmaceutical companies in the world have synthesized and evaluated in the clinic PDE4 inhibitors of varied structural classes.

It is the purpose of this chapter to describe the evolution of PDE4 inhibitors as novel anti-inflammatory drugs, the distribution of PDE4 across cells that participate in allergic and nonallergic inflammatory reactions, and potential sites where selective PDE4 inhibitors act to alleviate the inflammation associated with asthma and COPD. Clinical data are also provided for one PDE4 inhibitor, roflumilast (Daxas), which is in late-stage clinical development for both of these diseases.

## 4 STANDARDIZED NOMENCLATURE

A standardized GenBank nomenclature for existing and newly discovered PDEs was introduced in 1994 [45]. This taxonomy is based on traditional biochemical criteria and on protein sequencing and analyses of partial and full-length complementary deoxyribonucleic acid (cDNA) clones. Consider two hypothetical PDEs, CPPDE4D4B and HSPDE11A1A (Fig. 1). The first two letters refer to the species (CP for *Cavia porcellus*, HS for *Homo sapiens*). The next three letters plus an Arabic numeral correspond to the PDE gene family (i.e., PDE4, PDE11), while the next letter and Arabic numeral (i.e., D4, A1) denote the gene product and spliced variant (if appropriate). This nomenclature will be used throughout this chapter.

## 5 ROLIPRAM: A PROTOTYPE PDE4 INHIBITOR

One of the first selective inhibitors of PDE4 to be reported was rolipram (**1**) [46] together with the less

**TABLE 1 Properties and Selective Inhibitors of PDEs**

| PDE | Family | $K_m$ (μM) cAMP | $K_m$ (μM) cGMP | Selective Inhibitors |

| 11 | Dual selective | 1–2 | 2–3 | None reported |

[a]NA = Reliable data not available.

**Figure 1** GenBank nomenclature for the classification of PDEs. The first two letters (green) represent the species, the next three letters plus an Arabic numeral denote the PDE family (purple), the next letter and numeral refer to the gene product within the PDE family (red) and the spliced variant (if appropriate; orange), respectively, and the last letter indicates the report (yellow). See text for further details.

**Figure 2** Chemical structures of rolipram [**1**; (±) 4-[3-(cyclopentyloxy)-4-methoxyphenyl]pyrrolidin-2-one) and Ro 20,1724 (**2**; (+/–) 4-(3-butoxy-4-methoxyphenyl) imidazolidin-2-one]. Asterisk (*) denotes chiral center.

**Figure 3** Two pharmacophores of rolipram.

potent, structural analog, Ro-20,1724 (**2**) [47] (Fig. 2). Rolipram is composed of two pharmacophores: a 3-cyclopentoxy-4-methyl group and a pyrrolidine-2-one, which is also known as a γ-lactam (Fig. 3). Depression was the first indication in which rolipram was evaluated clinically [48, 49], and initial studies reported good efficacy [50]. However, the optimism that resulted from these early data was short lived as subsequent trials were much less convincing and associated with side effects, of which nausea was particularly problematic [51]. A similar lack of efficacy was found in Parkinson's disease and, again, dosing was associated with episodes of nausea [52, 53]. Thus, nausea together with other gastrointestinal events of concern resulted in the development of rolipram being discontinued.

## 6 PDE4 INHIBITORS BEYOND ROLIPRAM

Despite the failure of rolipram, a large number of PDE4 inhibitor research programs have been initiated in the hope that emetic liability can be reduced or even eliminated (reviewed in [54]). Currently, several PDE4 inhibitors of varied structural class are in clinical development for asthma, COPD, as well as other disorders including Alzheimer's disease, memory impairment, and multiple sclerosis (Table 2; Fig. 4). However, none have yet reached the market, and many have been discontinued presumably due to lack of efficacy and/or dose-limited side effects*. Nevertheless, optimism for this class of compounds remains high, and a discussion of their potential therapeutic utility still remains topical.

## 7 PHOSPHODIESTERASE 4

A cAMP-specific PDE inhibited by Ro 20-1724, but largely unaffected by cyclic guanosine monophosphate (cGMP), was originally purified from canine kidney [55, 56] and was the first report of a member of a large family of similar proteins collectively known as PDE4 isoenzymes. Since that original description, PDE4s have been purified and partially characterized from a number of sources, including human monocytes [57] and human leukocytes [58]. Human recombinant proteins have also been heterologously expressed and purified to facilitate investigations of structure–function relationships and to aid in the identification of selective inhibitors by high-throughput screening [59]. Without apparent exception, PDE4 isoenzymes are acid proteins ($p$I = 4–6) and exclusively hydrolyse cAMP.

In 1989 Davies and colleagues isolated and cloned the *Drosophila melanogaster dunce* gene and found that it encoded a PDE of the PDE4 family. In the same year four rat cDNA homologs [60–62] of the *dunce* cAMP PDE were identified, establishing a molecular basis for the observed heterogeneity of gene products within the PDE4 family. These clones represent transcripts of four different genes and are now named *RNPDE4A*, *RNPDE4B*, *RNPDE4C*, and *RNPDE4D* according to the nomenclature proposed by Beavo and colleagues [45] (see Fig. 1 for details). Four human genes (*A* to *D*) have also been identified and many of their products studied in some detail (see ref. 38) [39]. An astonishing finding that emerged from the molecular cloning of PDE4 isoenzymes is the presence of (messenger ribonuclerc acid (mRNA) transcripts of different sizes for

*The PDE4 inhibitor roflumilast (Daxas/Daliresp) was recently approved in the European Union and in the USA for the treatment of a subpopulation of patients with severe COPD.

**TABLE 2 Development State of PDE4 Inhibitors**

| Company | Drug | Indication | Development Stage |
|---|---|---|---|
| Almirall | Arofylline | Bronchitis | Phase II/III |
| Glenmark | Oglemilast (GRC 3886) | Asthma, COPD | Phase II |
| Pfizer | Tofimilast (CP-325366) | Asthma | Discontinued |
| ONO | ONO 6126 | Asthma, COPD | Phase II |
| Otsuka | Tetomilast (OPC 6535) | COPD | Phase III |
| Nycomed | Roflumilast | Asthma, COPD | Phase III |
| GlaxoSmithKline | Cilomilast (SB 207499) | COPD | Discontinued |
| GlaxoSmithKline | AWD-12-281 (GSK 842470) | Asthma | Discontinued |
| Celgene | Apremilast (CC-10004) | Asthma | Phase II |
| ICOS | IC-485 | COPD | Discontinued |
| MediciNova | Ibudilast | Multiple sclerosis | Phase II |
| Helican Therapeutics[a] | IPL-455903 (HT-0712) | Memory impairment | Phase II |
| Pfizer | UK-500,001 | COPD | Phase II[b] |
| Merck | MK-0952 | Alzheimer's disease | Phase II |

each of the four variants (greater than 20 have been unequivocally identified at the time of this writing) that are differentially expressed between tissues [38, 39, 63]. The basis for this profound heterogeneity of PDE4 isoenzymes is attributable to both alternative mRNA splicing and to the fact that the *PDE4* genes express multiple promoter regions and, therefore, provide several potential start codons for the translation of the protein.

Proteins encoded by each *PDE4* gene may be either "long," "short," or "supershort" (see ref. 38) [64]. Structurally, long PDE4 isoforms have an N-terminal domain, two, so-called, upstream conserved regions (UCR1 and UCR2; thought to mediate dimerization through ionic interactions [65, 66]), a highly conserved catalytic center and a unique C-terminus; in contrast, short PDE4 variants lack UCR1, whereas supershort isoenzymes also have a truncated UCR2 [67]. Long isoenzymes are encoded by all *PDE4* genes, whereas, apparently, only *PDE4A*, *PDE4B*, and *PDE4D* encode short forms [64].

### 7.1 Regulation of PDE4 by Protein Kinesis A (PKA)

PDE4 is subject to both short and long-term regulation by agents that elevate cAMP. This finding has led to the proposal (see ref. 68) that upregulation of PDE4 in allergic asthma could *contribute* to the tolerance of airway smooth muscle cells to the bronchodilator and protective effects of $\beta_2$-adrenoceptor agonists [69–78]. Indeed, a meta-analysis of 22 independent randomized, placebo-controlled studies conducted between 1989 and 2001 lead the authors to conclude that regular use of $\beta_2$-adrenoceptor agonists for at least one week in patients with asthma results in tolerance to the drug's bronchodilator activity and that this may be associated with poorer asthma control [72]. It is pertinent to mention that the mechanism of tolerance is not restricted to $\beta_2$-adrenoceptor desensitization. It is likely that in many subjects poor asthma control reduces the efficacy of $\beta_2$-adrenoceptor agonists. For example, mucus impaction may limit the delivery of drug to the desired sites of action and so compromise efficacy by physical means.

Upregulation of PDE4 can occur through either posttranslational modification (e.g., phosphorylation) of existing enzyme or gene induction. PKA was originally shown to phosphorylate the long PDE4 isoform, PDE4D3, at two serine resides: $S^{13}$, located within the unique N-terminus of the protein, and $S^{54}$, located at the beginning of UCR1 [79–85]. Phosphorylation at this second serine residue activates the enzyme (6- to 8-fold) and also increases its sensitivity (100- to 300-fold) to inhibition by certain PDE4 inhibitors including RS 25344 and RS 33793 [80]. The effect on catalytic activity of PKA-mediated phosphorylation is not restricted to PDE4D3. A similar enhancement (~50%) of cAMP degradation occurs upon phosphorylation of the serine residue that corresponds to $S^{54}$ in PDE4D3 in many long isoforms, including PDE4A8, PDE4B1, PDE4C2, PDE4D5, PDE4D7, PDE4D8, and PDE4D9, although, for reasons not yet explained, sensitivity to PDE4 inhibitors is unchanged [85–87].

Similarly, prolonged activation of PKA can lead to the accumulation of certain short PDE4 isoforms. This effect is believed to be mediated by the phosphorylation of the transcription factor, cAMP response element bing protein (CREB) which leads to the generation of PDE4 mRNA from an intronic promoter [62, 87–89].

**Figure 4** PDE4 inhibitors that are in, or have been in, development for asthma and/or COPD.

With respect to $\beta_2$-adrenoceptors in the lung, it is the PDE4 isoenzyme family that is a primary regulator of cAMP metabolism [42]. In this paradigm, tolerance to $\beta_2$-adrenoceptor agonists is directly related to an increase in PDE activity. This effect would theoretically compromise cell signaling through all $G_s$-coupled receptors leading to heterologous desensitization of susceptible cells to cAMP-dependent events. It is hypothesized that this could occur as a direct consequence of regular treatment of asthmatic subjects with $\beta_2$-adrenoceptor agonists [68].

While generally ignored, the concept of increased cAMP PDE activity as a mechanism of reducing the sensitivity of cells to hormones and other agonists that interact with Gs-coupled receptors is not new. In fact, evidence that this phenomenon accounts for much of the reduced responsiveness that cells exhibit to chronic hormone exposure was provided in 1978 [90] and has since been documented in vitro in many cells implicated in the pathogenesis of asthma such as T lymphocytes, neutrophils, monocytes, macrophages, platelets, and airways smooth muscle (ASM) [90–102].

An important issue that arises from the aforementioned discussion is whether induction and/or phosphorylation of PDE4 can be demonstrated in immune/pro-inflammatory cells and in vivo in response to $\beta_2$-adrenoceptor agonists. Although limited data are available, the answer to both parts of this question is "Yes." Torphy and colleagues [101] demonstrated that the $\beta_2$-adrenoceptor agonist, salbutamol, and the selective PDE4 inhibitor, rolipram, when given in combination to the human monocytic cell line, U-937, increased PDE4 activity in a time-dependent manner. Significantly, this effect required new protein synthesis, indicating that the increase in enzyme activity was attributable to the induction of one or more PDE4 isogenes. Reverse transcription-PCR (polymerase chain reaction) and western analyses performed by the same authors demonstrated subsequently that salbutamol and rolipram increased the expression of PDE4A and PDE4B at the mRNA and protein levels. A similar investigation by Verghese et al. essentially confirmed these observations [102]. Thus, exposure of human peripheral blood monocytes and Mono Mac 6 cells to cAMP-elevating agents promoted the transcription of the PDE4A, B, and D isogenes with the generation of at least three distinct mRNA transcripts and proteins. Induction of PDE4 isogenes has also been reported in U-937 and Jurkat T cells in response to prolonged exposure to dibutyryl cAMP [103] and, more recently, the same phenomenon was documented in guinea pig macrophages [104], human T lymphocytes [91], human neutrophils [95], and human ASM cells [105]. In the latter study, upregulation of the PDE4D5 splice variant was described, and this may have a particular significance given that this isoform interacts preferentially with β-arrestins and may play a role in $\beta_2$-adrenoceptor desensitization [106, 107].

A consistent and highly significant finding is that the responsiveness of many cells in which PDE4 is induced to cAMP-generating agonists is restored, at least in part, by the addition of a PDE inhibitor providing compelling evidence that upregulation of PDE is a significant contributing factor in the development of tolerance. In 2000, Finney et al. [108] reported the upregulation of PDE4 in the lungs of rats treated chronically for 7 days with salbutamol. Thus, this phenomenon can be reproduced in vivo and may have clinical relevance in the development of tolerance following chronic use of $\beta_2$-adrenoceptor agonists.

### 7.2 Regulation of PDE4 by ERK

The catalytic subunit of all PDE4 isoenzymes, accept PDE4A, features an ERK consensus site that, when phosphorylated, results in either an increase or decrease in activity that is determined by the upstream conserved regions (UCRs). Thus, the ERK-mediated phosphorylation of long forms, short forms, and supershort forms is associated with an inhibition, activation, and weak inhibition of catalytic activity, respectively [109–111]. Thus, PDE4 activity can be either augmented or inhibited following activation of ERK that will be determined, to a large extent, by the complement of long *versus* short isoforms present in the cell of interest. With respect to airway inflammation such as seen in asthma and COPD, regulation of PDE4 activity by ERK-mediated phosphorylation may be highly relevant given that many pro-inflammatory cytokines and chemokines signal via activation of mitogen-activated protein kinase cascades.

## 8 ANTI-INFLAMMATORY EFFECTS OF PDE4 INHIBITORS IN VIVO

The actions of PDE inhibitors upon the acute (IgE-mediated) or chronic (pro-inflammatory/immunocompetent cell-mediated) consequences of allergen provocation in vivo have, in general, been documented in some detail and include studies of passive cutaneous anaphylaxis (PCA), cell infiltration into sites of inflammation, and microvascular leakage.

### 8.1 IgE-Mediated Processes

It seems unlikely that PDE inhibitors of any isoenzyme family reduce IgE levels in vivo. In humans, it is reported that ibudilast, which is an essentially nonselective PDE inhibitor [112], is without effect on IgE levels in asthmatic individuals [113]. Similarly, the elevated level of total serum IgE in a murine model of dermatitis caused by the repeated application of 2,4,6-trinitro-1-chlorobenzene is unaffected by oral administration of the PDE4 inhibitor rolipram [114].

In contrast, PDE4 inhibitors exhibit efficacy at reducing PCA reactions in rats, mice, and guinea pigs [115, 116]. Furthermore, rolipram is effective at reducing the infiltration of indium-labeled eosinophils in to the skin of guinea pigs following a PCA reaction [117]. Collectively, these data imply that PDE4 inhibitors can suppress the degranulation of IgE-bearing leukocytes and, therefore, allergen-induced mediator release. Further support for this proposal derives from studies in sensitized guinea pigs where rolipram, administered intravenously, inhibits antigen- but not leukotriene $D_4$ ($LTD_4$)-induced bronchoconstriction [118]. Thus, rolipram preferentially exerts an inhibitory influence at the level of mast cells and basophils rather than exerting a direct antispasmogenic action at the level of airway smooth muscle.

### 8.2 Pro-inflammatory Cell Infiltration

A large number of investigations (too many to describe individually herein) have evaluated the effect of PDE inhibitors upon the infiltration of pro-inflammatory cells into the airway lumen, skin, and eye of guinea pigs, rats, and, monkeys in responses to a variety of dissimilar stimuli including allergen. For example, pretreatment of sensitized guinea pigs with zardaverine, a mixed PDE3/4 inhibitor, markedly suppressed allergen-induced infiltration of eosinophils, macrophages, and neutrophils into the bronchoalveolar lavage (BAL) fluid to a level achieved with dexamethasone [119]. Qualitatively identical data have been reported for the PDE3/4 inhibitor, benafentrine, on platelet-activating factor (PAF)—and allergen-induced pulmonary eosinophil recruitment in guinea pigs after chronic (6 days) dosing [120, 121]. Studies conducted more recently with rolipram and second-generation PDE4 inhibitors including cilomilast, roflumilast, and AWD 12-281 have corroborated these findings both in the airways an in allergic cutaneous reactions [122–131].

Similarly, treatment of sensitized Cynomolgus monkeys with rolipram abrogates the pulmonary neutrophilia and eosinophilia, and airway hyperresponsiveness after multiple exposures to the antigen and is without effect on the immediate increase in airway resistance that follows acute antigen provocation [132]. Thus, these data are consistent with the findings that PDE4 inhibitors may be anti-inflammatory and act primarily to prevent the activation of immune cells in the lung rather than by exerting an antispasmogenic or spasmolytic effect the level of airway smooth muscle [118].

### 8.3 Microvascular Leakage and Edema

It is well recognized that microcirculations play an important role in inflammatory reactions. Under normal conditions, the endothelium lining the postcapillary microvenules in the skin and bronchial circulation (capillaries in the pulmonary vasculature) is largely impermeable to blood cells and to macromolecules; but following a pro-inflammatory insult, localized arteriolar vasodilatation occurs with a consequent increase in blood flow. This effect is induced by the liberation of pro-inflammatory mediators such as histamine and tachykinins. An increase in capillary and microvenular pressure then ensues, together with the liberation of other mediators such $LTD_4$, which contract directly the microvenular endothelial cells. Together, these effects, by increasing microvenular permeability, permit the loss of plasma proteins from the vascular compartment. Furthermore, the resulting increase in osmotic pressure due to loss of solute from the circulation leads to marked fluid exudation and to edema.

In guinea pigs, PDE4 inhibitors given by the intravenous, oral, or intratracheal route markedly attenuate PAF-induced microvascular leakage in both small and large airways and into the BAL fluid of anaesthetized guinea pigs [133–135].

The finding that rolipram is active when given directly into the airways indicates an important local action and highlights that systemic administration is not necessary for these compounds to exert an anti-inflammatory influence. This is an important observation since the administration of PDE4 inhibitors by the inhaled route could reduce untoward side effects while maintaining efficacy (see below).

Svensjo and colleagues [136] have reported that PDE4 and PDE3/4 inhibitors also attenuate the increase in microvascular permeability evoked by bradykinin in the hamster cheek pouch. Qualitatively identical results are obtained for the effect of rolipram and denbufylline upon arachidonate-induced edema in rodents [137].

## 9 CLINICAL PHARMACOLOGY OF PDE4 INHIBITORS

### 9.1 Roflumilast Clinical Development Program

Despite there having been many clinical trials of PDE4 inhibitors in asthma and COPD, there is a relative paucity of data in the public domain. Indeed, of those PDE4 inhibitors in phase II and phase III development for airway inflammatory diseases (see Table 2), information on only one of these—roflumilast (Daxas)—is available and these data are discussed here.

The results of two multicenter, double-blind, placebo-controlled phase III studies have been published following peer review. In one of those, which was conducted in 159 centers across Australia, Austria, Belgium, Canada, France, Germany, Hungary, Ireland, South Africa, Spain, and the United Kingdom, 1411 subjects were randomized to receive roflumilast orally (250 or 500 μg o.d. [once a day]) or placebo for 24 weeks [138]. The primary efficacy endpoint measures were change in postbronchodilator forced expiratory volume in 1 second ($FEV_1$) and health-related quality of life using the St. George's Respiratory Questionaire (SGRQ). Secondary measures included change from baseline in prebronchodilator $FEV_1$, FVC (forced vital capacity), $FEV_6$, $FEF_{25\text{-}75}$ (forced expiratory $flow_{25\text{-}75}$) and COPD exacerbations. Compared to placebo, roflumilast statistically improved lung function at both doses and at all time points over the 24 weeks of treatment at which measurements were made. At the end of the treatment

period postbronchodilator $FEV_1$ relative to placebo was increased by 74 and 97 mL for the 250 and 500-μg doses, respectively [138], and subjects had experienced fewer exacerbations in the active treatment groups (the mean exacerbation number per patient = 1.13, 1.03, and 0.75 for placebo, roflumilast 250 μg, and roflumilast 500 μg, respectively). In contrast, there was no significant difference in health-related quality of life as assessed by the SGRQ for any domain whether the effect of roflumilast was compared against baseline or placebo. With regard to secondary outcome measures, significant improvements in prebronchodilator $FEV_1$, postbronchodilator FVC, $FEV_6$, and $FEF_{25\text{-}75}$ were also reported [138].

Despite the apparently positive outcome of this roflumilast trial in COPD, certain claims made by Rabe and colleagues [138] in that publication have attracted criticisms, some of which merit highlighting here (see [139–143]). Notably, Bergmann [139] attests that if the *raw* data are analyzed (see [144]) there is, in fact, no significant difference at the end of the trial between the placebo and the roflumilast treatment groups. Thus, after 24 weeks of treatment $FEV_1$ relative to baseline was increased and decreased by 51 and 45 mL in those subjects that were given roflumilast (500 μg o.d.) and placebo, respectively [138]. If those data are corrected for the difference in mean baseline $FEV_1$ between the placebo and roflumilast treatment groups at the beginning of the trial (these were 1.57 and 1.50 L, respectively), then the absolute difference in $FEV_1$ at week 24 favors roflumilast by a mere 26 mL [i.e., (1.5 L + 0.05 L) – (1.57 L – 0.045 L) – (1.5 L + 0.05 L) = –0.25. This is neither statistically nor clinically meaningful. Bergmann [139] also challenges the statistical evaluation of exacerbation rate between the three treatment groups stating that a classical $\chi^2$ test returns a nonsignificant $P$ value of 0.48. Another valid criticism, leveled by Morice [140], is the assertion by Rabe and colleagues that the modest improvement in lung function was due to an anti-inflammatory effect of roflumilast. As indices of inflammation were not measured in this trial, it is remarkable that a statement to this effect is incorporated into the title of the paper. By their own admission [145], the authors of the study extrapolate this interpretation from experiments conducted with laboratory animals (which at best can be misleading) and from previously published data where cilomilast was found not to be a directly acting bronchodilator [146].

The results of the other phase III trial were published in July 2007 [147]. In this 159 multicenter, randomized, placebo-controlled, double-blind parallel group study, the effect of roflumilast (500 μg o.d.) was compared against placebo in 1513 subjects with severe COPD [Global Obstructive Lung Disease (GOLD) stages III and IV]. The efficacy endpoint measures were change in postbronchodilator $FEV_1$ and exacerbation rate per patient per year. The main secondary variable was health-related quality of life using the SGRQ. Prebronchodilator $FEV_1$ postbronchodilator $FEV_6$, FVC, and $FEF_{25\text{-}75}$ were also determined. Inclusion and exclusion criteria were typical of most studies of PDE4 inhibitors in COPD except that previously prescribed inhaled corticosteroid (ICS) use was permitted. Compared to placebo, roflumilast improved lung function at all time points over the 52 weeks of treatment at which measurements were made. At the end of the treatment period postbronchodilator $FEV_1$ relative to placebo was increased by 39 mL; similar modest improvements in the other indices of lung function relative to placebo were also recorded, demonstrating that these effects can be maintained over a period of 1 year. However, there was no associated difference in the exacerbation rate between the two treatment groups (0.92 and 0.86 exacerbations/subject/year for placebo and roflumilast, respectively) or in health status. Calverley et al., [147] also performed a retrospective analysis of exacerbation frequency in those subjects characterized with GOLD stage IV disease. In that subpopulation, the exacerbation rate was 36% lower in subjects treated with roflumilast when compared to those given placebo (1.01 and 1.59 exacerbations/patient/year, respectively).

### 9.2 Assessment of the Roflumilast Clinical Development Program

The improvement in lung function effected by roflumilast in both of the aforementioned phase III clinical trials was modest and of similar magnitude to that evoked by ICSs. While these data are probably of limited clinical significance, the improvement in lung function reported by Calverley et al., [147] was evoked in subjects in whom the use of ICSs was permitted. Thus, perhaps roflumilast (and other PDE4 inhibitors) can improve lung function beyond that achievable by ICSs alone, despite the limited responsiveness of these subjects to bronchodilators [147].

It is worth noting that a meta-analysis of 13 clinical studies involving 244 subjects found that oral theophylline, a nonselective PDE inhibitor, improves $FEV_1$ in subjects with stable COPD by approximately 100 mL [148], which is superior to that produced by roflumilast in the phase III efficacy trials described here. These data may suggest that PDE4 inhibitors could further improve lung function if given at higher doses. Regrettably, most of the second-generation PDE4 inhibitors evaluated in clinical trials thus far conducted have been given at the highest tolerated dose, so this possibility cannot be

tested empirically. Whether the therapeutic ratio of this class of compound can be improved is currently unclear. However, clinical trials are ongoing, with a variety of new PDE4 inhibitors including oglemilast and tetomilast (Table 2), and the result of those studies could be instructive.

### 9.3 Safety and Tolerability of PDE4 Inhibitors

Despite some encouraging data from the pivotal phase II and III studies of COPD, all PDE4 inhibitors thus far examined including cilomilast (now discontinued—see http://www.reuters.com/article/sphereNews/idUSL152723420071015?sp=true&view=sphere) and roflumilast are hampered by a low therapeutic ratio. This limitation became clear early on in the development of these compounds with nausea, diarrhea, abdominal pain, vomiting, and dyspepsia being the most common adverse events reported (reviewed in [149]) [150]. Indeed, the number of subjects failing to complete all controlled cilomilast trials conducted by GlaxoSmithKline (GSK) due to an adverse event was positively dose related across the 2.5-, 5-, 10-, 15-mg treatment groups (6.9, 12.8, 20.4, and 25.9% withdrawal, respectively) with gastrointestinal disturbances being the most prevalent [151]. Similarly, the most common adverse events related to roflumilast treatment are diarrhea, nausea, and headache [138, 147]. Unfortunately, the unwanted gastrointestinal actions, which are mediated both locally (i.e., in the gastrointestinal tract) and centrally, can be accounted for by the ubiquitous distribution of PDE4 isoforms across many tissues and represent an extension of the pharmacology of PDE4 inhibitors that is typical of first-generation compounds such as rolipram.

## 10 OPTIMIZING THE EFFICACY OF PDE4 INHIBITORS

### 10.1 Oral Dosing

In the short term a number of options are available that could result in PDE4 inhibitors with enhanced efficacy and an improved therapeutic ratio. Perhaps the most appealing is to synthesize compounds that are delivered topically (i.e., by inhalation) directly to the site of action. These compounds would not be bioavailable, and, thus, systemic consequences including emetic liability and a propensity to cause cardiovascular lesions should be minimized. This approach has been used in the past with the development of piclamilast (Rhone-Poulence Rorer—now Sanofi Aventis), AWD 12-241 (Elbion/GlaxoSmithKline), GSK 256066 (GlaxoSmithKline), and tofimilast (Pfizer) but, as yet, no PDE4 inhibitor of this type has reached the market.

### 10.2 Combination Therapies

Other possibilities of harnessing the therapeutic potential of PDE4 inhibitors are through the development of combination therapies. Indeed, clinical trials are underway with PDE4 inhibitor/muscarinic $M_3$-receptor antagonist combinations (see http://www.clinicaltrials.gov/ct/search;jsessionid=628D4D1FDE10D07C7D6651C13193C47E?term=roflumilast) and UCB Pharma have recently published on UCB 101333-3, a 4,6-diaminopyridine derivative, which is a potent dual $M_3$-receptor antagonist *and* PDE4 inhibitor [152]. Such an approach could be more effective than either therapy alone as these drugs should improve lung function by interacting with complementary but mechanistically distinct processes. Combining an inhaled PDE4 inhibitor with an ICS could also afford greater clinical benefit than either drug given as a monotherapy in the same way that long-acting $\beta_2$-adrenocepotor agonist (LABA)/ICS combinations deliver superior efficacy [153]. The prospect of triple combination therapies incorporating a (ultra)LABA, ICS, and inhaled PDE4 inhibitor is also an appealing pharmacotherapeutic strategy.

### 10.3 Nonselective PDE Inhibitors

Theophylline has been shown to improve $FEV_1$ in subjects with COPD by at least 100 mL [148]. Based on this improvement in lung function, it is tempting to speculate that nonselective PDE inhibitors not based on the xanthine nucleus, which evokes many of the serious side effects reported with theophylline use, may prove to be the best therapeutic strategy for enhancing efficacy. Indeed, concurrent inhibition of multiple PDEs could exert clinically relevant effects, not produced by selective PDE4 inhibition, on processes that contribute to the pathogenesis of chronic airflow limitation, including airway remodeling (PDE1-regulated), endothelial cell permeability (PDE2-regulated), mast cell stabilization (PDE3-mediated), airway smooth muscle tone (PDE3-regulated), and remodeling of the pulmonary vasculature (PDE5-regulated) [154].

### 10.4 Subtype-Selective Inhibitors

Studies in mice in which three of the four PDE4 genes have been deleted indicate that they encode proteins that generally regulate specific, nonredundant functions [155]. Accordingly, it is possible that selective inhibition, with small-molecule inhibitors, of proteins derived from the transcription of a specific gene may allow the benefi-

cial effects of nonselective compounds to be retained while, at the same time, reducing or eliminating adverse effects. Indeed, using a surrogate measure, mice deficient in PDE4D display enhanced emetic behavior, whereas experimentally induced inflammation is relatively unaffected. In contrast, neither deletion of *PDE4A* nor *PDE4B* in mice is emetic, yet airway inflammation in vivo and cytokine generation from leukocytes ex vivo is markedly suppressed [156–159].

## 11 CONCLUDING REMARKS

The decision by the pharmaceutical industry to develop second-generation PDE4 inhibitors for the treatment of allergic and nonallergic inflammatory diseases of the airways is based on a conceptually robust hypothesis that is supported by a wealth of preclinical data. Therefore, if shown to be potentially disease modifying in clinical trials, PDE4 inhibitors will offer physicians a novel class of drug to treat patients with inflammation that may be refractory to other drugs such as glucocorticoids. That said, it is the view of this author that further major refinements in the design and/or use of PDE4 inhibitors are still necessary to improve their therapeutic ratio if major clinical benefit is to be achieved. Several options are available, and some of these are currently being evaluated in clinical trials. Thus, it is likely that several more years will elapse before we can assess whether the initial optimism in PDE4 inhibitors will be realized.

# DRUG INTERACTIONS FOR THERAPEUTIC PROTEINS: A JOURNEY JUST BEGINNING

HONGHUI ZHOU and BERND MEIBOHM

## 1.1 INTRODUCTION

Over the last three decades, therapeutic proteins, in particular, antibody-based biotherapeutics, have played an increasingly important role in pharmacotherapy, and in some therapeutic areas, such as immune-mediated inflammatory diseases (IMIDs) and oncology, therapeutic proteins have fundamentally changed the therapeutic paradigm. Therapeutic proteins have also presented enormous commercial potential. For example, the top 10 antibody-based biotherapeutics accounted for around $50 billion of worldwide sales in 2011.[1] The majority of these are either in IMID (adalimumab, etanercept, infliximab, rituximab, natalizumab, omalizumab) or in oncology (rituximab, bevacizumab, trastuzumab, cetuximab) therapeutic areas. Hundreds of investigational antibody-based and other protein therapeutics are currently under development at different stages, spanning discovery to phase III clinical investigations.

Owing to an expected increase in the coadministration of biotherapeutic agents with established pharmacotherapy regimens, there is an increasing likelihood for the occurrence of clinically relevant drug interactions. Therapeutic proteins, however, have long been perceived to have a very low propensity for drug–drug interactions because they are eliminated via catabolic routes, either nonspecific pathways or target-mediated pathways, that are independent from the elimination pathways of small molecules, which are usually eliminated by noncatabolic pathways such as hepatic metabolism via cytochrome P450 (CYP), renal excretion, and biliary excretion. Though it has been known for decades that some cytokines such as interferons, tumor necrosis factor α (TNF-α), and

interleukin 6 (IL-6) can down-regulate CYPs,[2] very few drug–drug interactions had been reported for biotherapeutics until 2007, when two review articles containing examples of drug interactions involving therapeutic proteins were published.[3,4] The majority of reported drug interactions associated with therapeutic proteins seem to be indirect; however, a mechanistic understanding for many of the observed interactions is still lacking.[5–7]

## 1.2 SCIENTIFIC/REGULATORY LANDSCAPE OF THERAPEUTIC PROTEIN–DRUG INTERACTIONS

To help assess the common practice of evaluating therapeutic protein–drug interactions across the biotech/pharma industry and to shed some light on how and when a sensible therapeutic protein–drug interaction assessment strategy should be incorporated into therapeutic protein drug development, a survey was conducted within the Biotechnology Industry Organization (BIO) member companies in 2010. It is not surprising that a majority of the responder companies did not have internal strategies for evaluating therapeutic protein–drug interactions at the time of the survey. Nevertheless, the most favored approach employed to address potential drug–drug interactions of therapeutic proteins at that time was a tailored and integrated (i.e., case-by-case) strategy that addressed the possibility of the therapeutic protein acting as either an initiator (perpetrator) or target (victim) of the interaction. Despite the fact that many of the companies responding to the survey reported drug–drug interactions involving therapeutic proteins, the majority of the clinical therapeutic protein–drug interactions studied did not warrant dose adjustment. In other words, most of the observed clinical therapeutic protein–drug interactions did not reach a clinically significant level. Routine *in vitro* screening and preclinical drug–drug interaction studies were not widely used for the evaluation of therapeutic proteins. For clinical development, dedicated clinical pharmacology drug–drug interaction studies were the most frequently used methodology, followed by population pharmacokinetics-based and clinical cocktail approaches.[8]

The BIO survey results indicated that there was a pressing need to have a science-driven and risk-based assessment strategy for therapeutic protein–drug interactions (TP-DIs). A closer collaboration among scientists from the biotech/pharma industry, regulatory agencies, and academia appeared to be essential in reaching that goal. As a result, a TP-DI steering committee from industry, the FDA, and academia was founded in 2009 to address this challenge. The initial scope of this committee was focused only on pharmacokinetics (PK) and metabolism-based drug–drug interactions for the major classes of therapeutic proteins, including monoclonal antibodies, fusion proteins, cytokines (excluding antibody–drug conjugates). The committee intended to investigate the potential for therapeutic proteins to interact, either as initiators or targets, with drugs that are metabolized via CYP enzyme pathways. Two major focus areas the committee concentrated on were (1) to critically assess standard *in vitro* screening techniques and methodologies

(e.g., for cytokine-related drug–drug and drug–disease interactions) and (2) to provide guidance for study designs with consideration of specific disease area (e.g., oncology) issues and timings.

Several scientific knowledge gaps were identified from a 2010 American Association of Pharmaceutical Scientists (AAPS) workshop on Strategies to Address Therapeutic Protein-Drug Interactions during Clinical Development.[9] One gap was associated with the relevance of *in vitro* systems to assess potential therapeutic protein–drug interactions, and another gap was a lack of best practices for using population PK-based approaches to assess potential therapeutic protein–drug interactions. The steering committee also identified similar gaps and consequently formed two working groups to specifically tackle them.

During the same time period, scientists from the FDA published two important review articles on TP-DI, but these were mostly from a regulatory perspective.[10,11] In 2012, a draft of a new drug–drug interaction guidance document was made available by the FDA for public comments.[12] That draft included a dedicated section on therapeutic protein–drug interaction to address specifically the newly emerging area of drug–drug interactions with therapeutic proteins.

The Workshop on Recent Advances in the Investigation of Therapeutic Protein Drug-Drug Interactions: Preclinical and Clinical Approaches was held on June 4–5, 2012. The workshop, co-sponsored by the FDA Office of Clinical Pharmacology and the Drug Metabolism and Clinical Pharmacology Leadership Group of the IQ Consortium, was intended to facilitate a better understanding of the current science, investigative approaches, knowledge gaps, and regulatory requirements related to the evaluation of therapeutic protein–drug interactions. The workshop also provided an opportunity to discuss the current views from the two (*in vitro* and population PK approaches) therapeutic protein–drug interaction working groups. The proceedings from this workshop are being compiled with the intent of issuing white papers in these subject areas. It is anticipated that the recommendations from both white papers will soon provide pharmaceutical scientists with sensible and scientifically sound best practices and an assessment framework for using *in vitro* and population PK-based approaches for evaluating therapeutic protein–drug interactions.

Our current understanding of the mechanisms of many therapeutic protein–drug interactions is still in its infancy. Much basic research needs to be conducted to verify several existing hypotheses related to therapeutic protein–drug interactions. Continued close collaborations among fellow scientists in industry, academia, and regulatory agencies will be vital to generate more plausible mechanistic hypotheses and collectively address the many challenges in this area. Through these collaborative efforts, the knowledgebase on therapeutic protein–drug interactions will likely be largely expanded in the near future, and it is hoped and anticipated that over the next decade a similar level of mechanistic understanding and systemic assessment methodology will be achieved and developed for drug interactions with protein therapeutics as it has been established in the last two decades for small molecule drugs. The journey toward that goal has just begun.

# PHARMACOKINETIC AND PHARMACODYNAMIC-BASED DRUG INTERACTIONS FOR THERAPEUTIC PROTEINS

DAN LU, SANDHYA GIRISH, FRANK-PETER THEIL, and AMITA JOSHI

## 2.1 INTRODUCTION

Therapeutic proteins (TPs) are protein products manufactured for pharmaceutical use. They include monoclonal antibodies (mAbs), antigen-binding fragments, antibody–drug conjugates (ADCs), cytokines, enzymes, growth factors, and miscellaneous proteins (e.g., fusion proteins and recombinant proteins). The development of therapeutic biologics, including TPs, is increasingly important in the pharmaceutical industry.[1] To achieve greater clinical benefits, TPs are often being combined with other TPs and small molecule drugs (SMDs). Whether drug interactions (DIs) in combination therapy result in an undesirable impact on efficacy and safety needs evaluation. To date, for the observed therapeutic protein–drug interactions (TP-DIs) that affect the exposure of TPs, only a modest change in exposure is observed and no impact on safety or efficacy has been documented, suggesting a limited clinical relevance.[2] This might be because most TPs have a relatively large therapeutic range compared to the majority of traditional SMDs. However, TP-DIs that affect the exposure of some drugs with a narrow therapeutic range (NTR), such as some SMDs and ADCs, may have an impact on efficacy and safety. The TP-DIs that result in enhanced toxicity due to undesirable pharmacodynamic (PD) interactions without a direct impact on exposures may also be clinically relevant. Thus the evaluation of TP-DIs is an important and evolving topic for the development of TPs in combination with other drugs.

This chapter reviews the major absorption, distribution, metabolism, and excretion (ADME) pathways of TPs, summarizes the potential mechanisms of

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad
Copyright © 2013 John Wiley & Sons, Inc.

pharmacokinetic (PK) and PD-based TP-DIs, and recommends a question-based TP-DI risk assessment strategy during clinical development. The DIs for some nonprotein biologics such as nucleic acid–based derivatives are reviewed in other chapters.

## 2.2 DISTRIBUTION, CATABOLISM/METABOLISM, AND EXCRETION MECHANISMS OF THERAPEUTIC PROTEINS

ADME processes determine the PK properties of SMDs and TPs. In drug combinations, one drug may impact the ADME processes of another drug, leading to a change in its exposure. For SMDs, absorption is mainly mediated by the solubility and permeability of a SMD and its interaction with transporters. Distribution of SMDs is mediated by several key processes, such as blood perfusion, permeability across membrane barriers, and nonspecific binding. Metabolism of SMDs is mainly mediated by cytochrome P450 (CYP) and non-CYP enzymes (such as *N*-acetyl and glucuronyl transferase). Excretion of SMDs mainly occurs via renal filtration or renal and biliary secretion mediated by transporters.[3] Figure 2-1*a* depicts the typical clearance pathways for SMDs.

For TPs, ADME processes are different from SMDs.[4–6] Owing to high gastrointestinal enzyme activity and low permeability through the gastrointestinal mucosa, most TPs are not therapeutically active on oral administration. Consequently other routes of administration, such as intravenous, subcutaneous, and intramuscular routes of injection are used for TPs.[6] For subcutaneous injections of TPs with large molecular weight, convective transport across local lymphatic vessels is the major mechanism of absorption from the injection site.[7] The processes of distribution, catabolism, and excretion of TPs are reviewed in detail in this chapter. As illustrated in Figure 2-1*b*, the catabolism of TPs are mainly mediated by nonspecific clearance pathways. Target-mediated drug disposition (TMDD) and immunogenicity-mediated pathways also play roles in the clearance of some TPs. ADCs belong to a more complex group of TPs, made up of both a mAb and a small molecule cytotoxic agent. Their PK properties are also reviewed here.

**FIGURE 2-1** Comparison of clearance mechanisms of (a) a SMD and (b) a TP. CYP: cytochrome P450; FcRn: neonatal Fc receptor; SMD: small molecule drug; TMDD: target-mediated drug disposition; TP: therapeutic protein.

### 2.2.1 Distribution of Therapeutic Proteins

Distinct from most SMDs that widely distribute to various tissues and organs after administration, distribution of mAbs and large TPs is usually confined by their large size; consequently the molecules have limited mobility through membranes. This often results in a relatively small volume of distribution. The volume of distribution of mAbs and ADCs at steady state is often a low multiple (1 to 2) of physiologic plasma volume (approximately 50 mL/kg). This is similar to the distribution characteristics for an endogenous immunoglobulin G (IgG). The distribution of TPs outside the systemic circulation is mediated by limited interstitial penetration in various organs, convection-dominated lymphatic drainage, specific and nonspecific binding to peripheral tissues, and target-mediated cellular uptake. For TPs with relatively low molecular mass, preclinical study results have demonstrated better tissue penetration.[6] Unlike SMDs, transporters usually do not play a role in the distribution of large TPs.

### 2.2.2 Catabolism of Therapeutic Proteins

Most TPs are mainly catabolized by proteolytic degradation in cellular lysosomes through nonspecific pathways, resulting in peptides and amino acids that are reutilized for protein synthesis.[4,6] It is generally believed that nonspecific catabolism of TPs may take place predominantly in the lysosomes of endothelial cells and the mononuclear phagocyte system (MPS). TPs, such as mAbs and some fusion proteins containing a fragment crystallizable region (Fc region), interact with neonatal Fc receptors (FcRn) similar to endogenous IgGs. In adults, FcRn is primarily expressed in the vascular endothelial cells. FcRn is also detectable on monocytes, tissue macrophages, and dendritic cells. The FcRn-mediated recycling protects IgG type of proteins (e.g., endogenous IgGs, mAbs, and Fc fusion proteins) from proteolytic degradation in lysosomes, consequently delaying their catabolism and prolonging their half-lives compared to other types of proteins that are not rescued by FcRn-mediated recycling.[4,5] As a result, endogenous IgGs, mAbs, and Fc fusion proteins usually have relatively long half-lives, ranging from several days to weeks. The pathways of nonspecific clearance and FcRn-mediated recycling are typically low-affinity and high-capacity pathways, which are usually nonsaturable at therapeutically relevant doses. For mAbs, relatively constant values of nonspecific clearance are found in each species. In humans, this value is 3–6 mL/day/kg and is affected by multiple pathophysiological and demographical covariates.[8]

In addition to the nonspecific clearance pathways, TMDD may also play a role in the clearance of target-binding proteins (e.g., mAbs, Fc fusion proteins, recombinant proteins). By this mechanism, a TP is cleared from the systemic circulation by binding to its target antigen followed by proteolytic degradation. The target antigens can be cell-surface receptors or soluble antigens. For targets that are cell-surface receptors, a TP is cleared after the TP–antigen complex is internalized and degraded in the lysosomes of target cells or when the TP-opsonized cell engages in immune effector function, which triggers apoptosis of the target cells by

complement-dependent cytotoxicity and antibody-dependent cellular cytotoxicity followed by degradation of the TP. For targets that are soluble antigens, a TP is cleared after the TP–antigen complex is eliminated via phagocytosis and proteolysis by endothelial cells and MPS. TMDD is typically a high affinity, low capacity and saturable process. When TMDD plays an important role in TP clearance, the PK parameters of the TP is concentration and dose dependent and may show a time-dependent decrease of clearance if receptor capacity is decreased after repeated treatment. For example, efalizumab[9] and panitumumab[10] show higher clearance at low concentrations and doses in clinical applications. The clearances of gemtuzumab and rituximab decrease after the second dose compared to the first dose, which may result from the decrease of target-mediated clearance after a reduction in target tumor cell number after the first dose of treatment.[11] For most TPs with TMDD involvement, the TMDD pathway is usually more dominant at low doses and low concentrations of the TPs when this pathway is not saturated. At therapeutic doses of these TPs, the therapeutic protein is often in great excess compared to the expression level of the respective target antigen available for binding under equilibrium conditions; consequently, the nonspecific clearance pathways play a dominant role. For these TPs at their prescribing doses (e.g., pertuzumab,[12] bevacizumab,[13] and trastuzumab[14]), changes of target antigen levels generally have a minimal impact on their clearance, and their PK parameters are concentration and dose independent.

The ability of TPs to elicit humoral responses, i.e., immunogenicity, can often modulate the clearance of TPs. The humoral response leads to the formation of antitherapeutic antibodies (ATAs), which may form immunocomplexes with TPs and consequently affect the clearance rates by affecting the binding of a TP to its target or affecting the nonspecific clearance pathways. For example, accelerated clearance of infliximab and adalimumab has been reported after development of ATA in rheumatoid arthritis (RA) patients.[15,16]

### 2.2.3 Excretion of Therapeutic Proteins

Excretion mechanisms for TPs also differ from those for SMDs. Renal clearance is generally negligible when the molecular size of a TP exceeds the cutoff size for renal filtration of approximately 45 kDa.[17] Tubular secretion does not occur to any significant extent for large TPs. The peptides resulting from TP catabolism may be partially reabsorbed in the proximal or distal tubule of the nephron or are further catabolized in kidney. Biliary excretion of TPs has been reported for only some fragment peptides and proteins such as immunoglobulin A and octreotide,[6,18] which are subsequently degraded in the gastrointestinal tract.

### 2.2.4 Pharmacokinetic Properties of Antibody–Drug Conjugates

ADCs, as an emerging class of TPs, have the PK properties of both mAbs and SMDs. ADCs are composed of a potent cytotoxic agent conjugated to a mAb via various types of linkers.[19,20] ADCs bind to their target receptors on the surface of tumor cells. The complexes are internalized and degraded and subsequently release

the cytotoxic agents to kill tumor cells. Usually the PK properties of multiple analytes, such as the conjugate and the unconjugated cytotoxic agent, are assessed after administration of an antibody–drug conjugate.

To date all ADCs are administered intravenously.[20] The distribution of ADCs is similar to their unconjugated mAbs. For example, in a preclinical *in vivo* study, it was found that trastuzumab emtansine (T-DM1), an ADC for the treatment of human epidermal growth receptor 2 (HER2) positive solid tumors, had similar tissue distribution to that of trastuzumab, the mAb component of T-DM1, indicating that conjugation does not impact the distribution of trastuzumab.[21] ADCs are catabolized by similar pathways as mAbs, including nonspecific proteolytic degradation and TMDD pathways. Immunogenicity may also play a role in ADC clearance.

In addition, the processes of linker chemistry-determined deconjugation in plasma and tissue are also involved in the catabolism and clearance of ADCs. The formation rate of the small molecule cytotoxic component by catabolism of the ADC is usually much slower than the elimination clearance of the small molecule cytotoxic component itself, resulting in formation rate-limited pharmacokinetics. Upon formation, these unconjugated cytotoxic molecules undergo typical clearance pathways of SMDs, such as hepatic metabolism and renal and biliary excretion, as mediated by CYP, non-CYP enzymes, and transporters.[21,22] The low dose of the SMD component of an ADC and relatively slow formation rate combined with a relatively fast elimination rate of the unconjugated SMD molecules may explain the observed relatively low systemic exposure of the unconjugated cytotoxic agent. For example, the average maximal concentration of the derivative of maytansine (DM1) is ~5 ng/mL after the administration of 3.6 mg/kg of T-DM1 every 3 weeks.[22] The average maximal free monomethyl auristatin E (MMAE) concentrations are 5–7 ng/mL after the every-3-week administration of 1.8–2.7 mg/kg of brentuximab vedotin,[23] a MMAE-containing ADC.[24]

## 2.3 MAJOR MECHANISMS OF THERAPEUTIC PROTEIN–DRUG INTERACTIONS

We are categorizing DIs as either PK based or PD based. PK-based DIs are those resulting from direct competition, inhibition, or induction of drug ADME mechanisms without involvement of the therapeutic targets. PD-based DIs are those resulting from modulation of the systems or target biology via the PD effects of drugs in combination. Both PK- and PD-based DIs may result in relevant changes in exposure and lead to a potential impact on safety and efficacy outcomes, especially for drugs with a NTR. PD-based DIs may also cause undesirable toxicity without an impact on exposure. Unlike SMDs, which are often susceptible to PK-based DIs due to an alteration in CYP and transporter-mediated ADME processes by drug combinations,[3,25] TP-DIs are often mechanistically different.

### 2.3.1 Impact of Pharmacokinetic-Based Therapeutic Protein–Drug Interactions on the Exposures of Therapeutic Proteins and Small Molecule Drugs

PK-based TP-DIs are not common because TPs and SMDs have distinct PK properties. The nonspecific clearance pathways for TPs are usually unsaturable at therapeutic concentrations. Likewise, these pathways are unlikely to be saturated by the combination of two TPs. For example, the clearances of trastuzumab and bevacizumab are dominated by nonspecific pathways at their clinically efficacious doses. No alteration in PK properties is observed when they are given in combination.[26]

When a TP is combined with a SMD, there is usually no direct overlap and competition in the metabolism and clearance pathways, thus PK-based DIs are unlikely. For example, chemotherapeutic agents such as irinotecan, 5-fluorouracil, and platinum-based therapy (i.e., cisplatin, carboplatin) do not affect the PK properties of cetuximab in cancer patients.[27–29] Similarly, no PK-based DIs are observed between bevacizumab and any of the following agents: capecitabine, cisplatin, 5-fluorouracil, irinotecan, oxaliplatin, or paclitaxel.[30] A dedicated study was conducted to evaluate potential TP-DIs for the combination of bevacizumab and irinotecan (as part of the FOLFIRI regimen containing irinotecan, fluorouracil, and leucovorin). This study demonstrated that the 90% confidence interval of geometric mean ratios for exposure of irinotecan and SN-38 (the active metabolite of irinotecan) in the absence of versus in the presence of bevacizumab were both within the prespecified no effect boundaries, indicating no clinically relevant TP-DIs for this combination.[31] Additional examples of no TP-DIs for combinations of anticancer mAbs with chemotherapeutic and antineoplastic SMDs have been reviewed in recent publications.[2,30,32–35]

PK-based TP-DIs involving ADCs are theoretically possible because the cytotoxic component of the ADC, once deconjugated, may elicit PK-based DIs when the ADC is combined with other SMDs. The cytotoxic agent, which is often a CYP substrate, is likely a victim of DIs when combined with SMDs that are CYP inhibitors or inducers. However, the cytotoxic agent has a relatively low systemic exposure. Thus it is not expected to have any impact on CYP and transporter activities in clinical settings and is unlikely to be a perpetrator. Data for ADC-related DIs are limited to assessments for T-DM1 and brentuximab vedotin (Adcetris). When T-DM1 is given in combination with taxanes (paclitaxel or docetaxel), the PK properties of taxanes and DM1 remain unchanged because taxanes and DM1 are not potent CYP inhibitors or inducers at clinically relevant concentrations.[36,37] A dedicated study of brentuximab vedotin found that it does not affect the PK parameters of midazolam, a CYP3A4 substrate. In the same study, the unconjugated MMAE exposure increased ~34% when brentuximab vedotin was combined with ketoconazole (a potent CYP3A4 inhibitor) and decreased ~46% when brentuximab vedotin was combined with rifampin (a potent CYP3A4 inducer). Therefore it is recommended that patients who are receiving strong CYP3A4 inhibitors concomitantly with brentuximab vedotin should be closely monitored for MMAE-related adverse reactions. These results are expected because MMAE is a substrate of CYP3A4 but not a CYP inhibitor or inducer at clinically relevant concentrations.[23]

**FIGURE 2-2** Theoretical mechanisms of PD-based TP-DIs that change exposure of the TP. SMD: small molecule drug; TP: therapeutic protein.

### 2.3.2 Impact of Pharmacodynamic-Based Therapeutic Protein–Drug Interactions on the Exposure of Therapeutic Proteins

Distinct from the less common cases of PK-based TP-DIs, there are several plausible mechanisms for PD-based TP-DIs that change the exposure of TPs. As shown in Figure 2-2, interaction between the biological systems or target biology with a TP may affect the TP's exposure through immunogenicity-mediated clearance or target-mediated clearance pathways. The TPs or SMDs given in combination may modulate these clearance pathways by their PD effect, leading to DIs. For example, immunosuppressants such as methotrexate (MTX), mycophenolate mofetil, and azathioprine increase the exposures of infliximab, adalimumab, and basiliximab, possibly due to the effect of the immunosuppressants on decreasing the immunogenicity rate of these mAbs when they are given in combination. In another case, triple immunosuppressive agents may decrease target (CD11a+ T-cells) level, subsequently decreasing target-mediated clearance of efalizumab and thus increasing its exposure.

***2.3.2.1 Pharmacodynamic-Based Therapeutic Protein–Drug Interactions Owing to Changes in Immunogenicity-Mediated Clearance of Therapeutic Proteins*** Some immunosuppressive drugs may modulate the humoral immune response and decrease the immunogenicity of a TP, thus modulating its clearance. This is possible only for TPs that have a relatively high immunogenicity rate and when the clearances of TPs are impacted by immunogenicity. Examples include infliximab, adalimumab, and basiliximab, as listed in Table 2-1. Infliximab and adalimumab are both mAbs antagonizing tumor necrosis factor α (TNF-α)[44] and are often given in combination with immunosuppressive agents

**TABLE 2-1 Examples and Clinical Relevance of PD-Based TP-DIs That Have an Impact on PK Properties of TPs**

| Drug Combination | Type of TP and Indication | Possible Mechanisms for TP-DIs | Change in PK Properties | Clinical Relevance | References |
|---|---|---|---|---|---|
| Infliximab + MTX | Infliximab: anti-TNFα mAb<br>Indication: RA | MTX may inhibit humoral response; ↓ immunogenicity of infliximab. | MTX ↓ CL of infliximab. | No dose adjustment is recommended. | 38,39 |
| Adalimumab + MTX | Adalimumab: anti-TNFα mAb<br>Indication: RA | MTX may inhibit humoral response; ↓ immunogenicity of adalimumab. | MTX ↓ CL of adalimumab by 29–44%. | No dose adjustment is recommended. | 15,40 |
| Basiliximab + CsA + corticosteroids + mycophenolate mofetil or azathioprine | Basiliximab: chimeric mAb against IL-2Rα on T-cells<br>Indication: prevent transplant rejection | Mycophenolate mofetil or azathioprine may inhibit humoral response; ↓ immunogenicity of basiliximab. | Mycophenolate mofetil ↓ CL of basiliximab by 51%; azathioprine ↓ CL of basiliximab by 22%. | No dose adjustment is recommended. | 41,42 |
| Efalizumab + triple immunosuppressive agents (CsA, sirolimus, prednisone) | Efalizumab: humanized IgG1 anti-CD11a mAb<br>Indication: psoriasis, prevent transplant rejection | Triple immunosuppressive agents may ↓ TMDD of efalizumab by suppression of CD11a+ T-cells. | Triple immunosuppressive agents ↓ CL of efalizumab by 50% in transplant patients compared to psoriasis patients. | No dose adjustment is recommended. | 43 |

CL: clearance; CsA: cyclosporine; IL-2R: interleukin 2 receptor; mAb: monoclonal antibody; MTX: methotrexate; PD: pharmacodynamic; PK: pharmacokinetic; RA: rheumatoid arthritis; TMDD: target-mediated drug disposition; TNF: tumor necrosis factor; TPs: therapeutic proteins; TP-DIs: therapeutic protein–drug interactions.

such as MTX for the treatment of autoimmune diseases and prevention of rejection after organ transplantation. It was found that patients with positive ATA responses needed higher doses of infliximab to maintain the therapeutic concentration.[16] Similarly, serum trough adalimumab concentrations were dramatically lower in patients who developed antiadalimumab antibodies.[15] Concomitant dosing of MTX was associated with a decreased incidence of ATA formation against infliximab[38,45] and adalimumab.[15,45] As a result, when given in combination with MTX, the clearance of infliximab and adalimumab decreased and their serum concentrations increased.[15,38,40,44,45]

Basiliximab is a high-affinity chimeric IgG1-based mAb that binds to and blocks the interleukin 2 receptor α-chain (IL-2Rα) on the surface of activated T-lymphocytes and competitively inhibits IL-2-mediated activation of lymphocytes, a critical pathway in the cellular immune response involved in allograft rejection.[41] Basiliximab is often given in combination with triple immunosuppressive agents, including cyclosporine (CsA), corticosteroids, and either azathioprine or mycophenolate mofetil to prevent renal allograft rejection.[42] A cross-study comparison of basiliximab PK parameters in *de novo* renal allograft recipients showed that basiliximab clearance was $29 \pm 14$ mL/h when coadministered with azathioprine and $18 \pm 8$ mL/h with mycophenolate mofetil, and both were significantly lower compared to a clearance of $37 \pm 15$ mL/h from an earlier study of basiliximab with dual immunosuppressive agents of CsA and corticosteroids only.

Although the interstudy variability could potentially be a caveat of this observation, a plausible reason is that immunosuppressive agents such as azathioprine and mycophenolate mofetil may inhibit humoral immune responses and consequently decrease basiliximab clearance. Mycophenolate mofetil may have a stronger inhibition effect than azathioprine. The immunogenicity data in these studies further suggest that if the reduced clearance of basiliximab in the presence of azathioprine or mycophenolate mofetil is due to an inhibition of humoral immune responses, it appears that these responses are directed to a portion of basiliximab other than the IL-2Rα binding portion of basiliximab. Nonetheless, the PD effect of basiliximab as indicated by the range of the durations of IL-2Rα saturation when basiliximab was combined with triple immunosuppressive agents did not extend outside the range of the durations after the treatment of basiliximab in combination with dual immunosuppressive agents. Hence, regardless of the observed clearance difference, no dosing adjustment was necessary.[42]

***2.3.2.2 Pharmacodynamic-Based Therapeutic Protein–Drug Interactions Owing to Changes in Target-Mediated Drug Disposition of Therapeutic Proteins*** Combinations that affect the TMDD pathway of some TPs may result in PD-based TP-DIs, when TMDD plays an important role in the clearance processes of these TPs at their therapeutic doses. Based on a theoretical simulation of a typical mAb with strong TMDD (i.e., TMDD accounts for >50% of total clearance in the therapeutically relevant dose range), an increase of baseline receptor expression level (e.g., 3-fold or 10-fold of baseline) leads to a significant increase of the observed total clearance; a decrease of baseline receptor expression

level (e.g., 10%, 30% of baseline) leads to a significant decrease of the observed total clearance. The magnitudes of changes are higher at low dose levels, when TMDD accounts for higher percentage of total clearance (Figure 2-3*a*).

A clinical example is efalizumab in combination with immunosuppressive agents for preventing organ rejection after transplantation, is listed in Table 2-1. At clinical doses, TMDD of efalizumab after binding with CD11a receptors expressed on T-cells plays an important role in efalizumab clearance. Consequently, clearance of efalizumab is concentration and dose dependent and governed by CD11a expression level.[48] When efalizumab was given by subcutaneous administration in combination with oral administration of triple immunosuppressive agents (CsA, sirolimus, and prednisone) in transplant recipients, the clearance of efalizumab was 50% lower than the clearance observed in psoriatic patients. One of the reasons might be related to the reduction of CD11a+ T-cells in circulation by immunosuppressive agents given in combination in transplant recipients, resulting in reduced TMDD of efalizumab.[43,48]

However, in most clinical situations in which TPs are given at efficacious doses at which the TMDD pathway does not play a major role in their clearance, the nonspecific proteolytic degradation pathways, which are usually of high capacity and unsaturable, dominate the clearance of these TPs. They exhibit linear PK characteristics with relatively constant total clearance at therapeutic doses. For these TPs, the possibility of PD-based TP-DIs as a result of a target receptor expression level change by the combination drug is usually low. Based on a theoretical simulation of a typical mAb with negligible TMDD (i.e., TMDD accounts for $\leq$1% of total clearance in the therapeutically relevant dose range), an increase or a decrease of baseline receptor expression level (e.g., 3-fold, 10-fold, 10%, or 30% of baseline) does not have a significant impact on the observed total clearance (Figure 2-3*b*).

A clinical example is the combination of T-DM1 with pertuzumab, an ADC with a mAb.[49] Both the trastuzumab component of T-DM1 and pertuzumab bind to

**FIGURE 2-3** Effect of receptor expression level on the dose-total CL relationship for a typical mAb. Observed total CL = dose/area under the concentration–time profile. Simulation is performed using a standard TMDD model after a single dose of a typical mAb [46,47]. The baseline free receptor expression levels was altered to 3-fold, 10-fold, 10%, or 30% of baseline, and the observed total CL values were plotted versus dose levels. (a) TMDD accounts for >50% of total clearance in the therapeutically relevant dose range. (b) TMDD accounts for $\leq$1% of total clearance in the therapeutically relevant dose range. CL: clearance.

HER2 receptors. Therefore a potential for PD-based DIs might exist for this combination. However, pertuzumab and T-DM1 bind to distinct epitopes of HER2 simultaneously without steric hindrance.[50,51] Furthermore, both T-DM1 and pertuzumab have linear PK characteristics at their clinically efficacious dose ranges when given in combination,[12,22] indicating that HER2-mediated clearance is unlikely to play a major role in their clearance in these dose ranges. Hence a potential impact on HER2 biology by T-DM1 is unlikely to affect the PK characteristics of pertuzumab, and vice versa. Cross-study comparisons of PK parameters of T-DM1 and pertuzumab in the combination study and the historical single-agent studies demonstrate that there is no DI observed for this combination.[49]

### 2.3.3 Impact of Pharmacodynamic-Based Therapeutic Protein–Drug Interactions on the Exposure of Small Molecule Drugs Owing to Therapeutic Protein–Cytokine–Cytochrome P450 Modulation Effects

Because TPs and SMDs do not share common ADME mechanisms, TPs are not predicted to affect the hepatic, renal, or biliary elimination of SMDs directly. However, some immunomodulatory TPs may exert an indirect effect on the hepatic clearance pathways of SMDs through the TP-cytokine-CYP modulation effect, resulting in PD-based TP-DIs. As summarized in Figure 2-4, infection and inflammatory diseases may cause an elevation of systemic cytokine level, such as interferons (IFNs), interleukins, and tumor necrosis factors, which in turn inhibit the CYP

**FIGURE 2-4** Theoretical mechanisms of PD-based TP-DIs that have an impact on the PK properties of SMDs through TP-cytokine-CYP modulation effect. CYP: cytochrome P450; IFN: interferon; IL: interleukin; SMD: small molecule drug; TNF: tumor necrosis factor; TP: therapeutic protein.

activity and consequently increase the exposure of SMDs that are CYP substrates.[52] Some immunomodulatory TPs, such as exogenous IFNα, muromanab-CD3, and basiliximab may upregulate certain cytokine levels, inhibit CYP activities, and increase the exposure of CYP substrates (e.g., theophylline, cyclophosphamide, CsA, and tacrolimus). In contrast, some immunomodulatory TPs such as tocilizumab may downregulate the pathologically elevated cytokine levels in the inflammation disease state, normalize CYP activities to a higher level similar to healthy individuals, and decrease the exposure of CYP substrates (e.g., omeprazole, simvastatin). In addition to these clinical observations, there is strong *in vitro* evidence suggesting the differential effects of cytokines on various CYP enzymes.[1] The TP-DIs induced by the TP-cytokine-CYP modulation effect may be clinically relevant for SMDs with a NTR. The mechanisms and various scenarios of this type of TP-DI are reviewed in detail in this section.

Pathophysiological changes in patients and animal models in infectious or inflammatory conditions are often associated with decreased production and activities of hepatic and intestinal CYP enzymes, which are important for the first-pass extraction and metabolism of most SMDs. Based on *in vitro* and *in vivo* data, proinflammatory cytokines such as ILs (IL-1β, IL-6), TNFs (TNFα), and IFNs (IFNγ, IFNα-2b) may be potentially important mediators of this CYP modulation effect. These cytokines may induce a decrease in transcription factor activity for CYP enzyme expression or a decrease in CYP enzyme stability. As a result, CYP activities decrease in patients with infectious and inflammatory disease with elevated proinflammatory cytokine levels. The patients usually have an increased exposure of the SMDs metabolized by CYP enzymes because of decreased clearance and/or increased bioavailability compared with healthy individuals.[52]

Direct administration of exogenous cytokines may produce an immunopathological state similar to infection or inflammation, downregulate CYP activities, and potentially increase the exposure of some SMDs given in combination.[52] For instance, a clinical study using the "Pittsburgh cocktail" approach in high-risk melanoma patients found that the high-dose IFNα-2b[53] therapy differentially impairs CYP-mediated metabolism, causing no effect on some enzymes (e.g., CYP2E1) but substantial effects on others (e.g., CYP1A2: median 60% activity decrease; CYP2C19, median 40% activity decrease).[54] IFNα-2b has also been used in combination with theophylline for the treatment of various diseases (e.g., chronic hepatitis B). The clearance of theophylline, a CYP1A2 substrate drug with a NTR, decreased after IFNα-2b treatment, resulting in a 100% increase in serum theophylline levels.[53] In a clinical study in multiple myeloma patients, it was found that the administration of IFNα before cyclophosphamide (CP) caused a decrease in CP clearance to 63%, a 137% longer half-life and a 137% higher peak plasma concentration compared to the results obtained when IFNα was administered 24 h after CP. Consequently, the active metabolite 4-hydroxycyclophosphamide, which is formed by CYP-mediated metabolism from the prodrug CP, had 45% lower exposure when IFNα was given before CP compared with that observed when IFNα was administered 24 h after CP. As a result, a significant decrease in leukocyte count was observed when IFNα was given 24 h after CP.[55] These examples (some of them are listed in Table 2-2) demonstrate the

**TABLE 2-2 Examples and Clinical Relevance of TP-DIs Affecting the PK Properties of SMDs Caused by the TP-Cytokine-CYP Modulation Effect**

effect of exogenous cytokines on the activity of CYPs in the clinical setting, which implies that endogenous cytokine levels may play an important role as modulators of hepatic metabolism.

Similarly, some mAbs may increase cytokine levels and activities by their PD effects and may lead to similar effects as the treatment by exogenous cytokines. As listed in Table 2-2, both muromonab-CD3 and basiliximab are mAbs for preventing rejection after organ transplantation.[41,56] Muromonab-CD3 is a murine IgG2a mAb targeting CD3 on T-cells to prevent acute organ rejection. Immediately after administration of muromonab-CD3, the activation of T-cells and release of numerous cytokines are observed followed by the blocking of all known T-cell functions. The initial T-cell activation and cytokine release may downregulate CYP enzyme activity and expression. CsA is a CYP3A4 substrate that may be combined with muromonab-CD3 in transplantation patients. It was found that muromonab-CD3 treatment caused a significant rise in CsA trough levels at day 5 post–renal transplantation compared to the group of patients receiving antilymphocyte globulin immunoprophylaxis therapy. As a result, CsA doses were adjusted based on trough levels obtained on day 5 post-transplantation.[57]

Clinically significant DIs were also reported for basiliximab in combination with CsA or tacrolimus. Both CsA and tacrolimus are metabolized by CYP3A4 and require therapeutic drug monitoring owing to their NTRs. In children who have undergone kidney transplant, basiliximab combination led to a higher trough concentration of CsA compared to the patients in the control group who were not on basiliximab. Consequently, it was recommended that the initial CsA dose should be limited to 400 $mg/m^2$ if used in combination with basiliximab in children with kidney transplants.[58]

Similarly, a 63% increase in tacrolimus trough levels was reported in basiliximab-treated adult patients on day 3 postrenal transplantation, when compared to the control group receiving antithymocyte globulin induction therapy without basiliximab treatment. As a result, the tacrolimus dose was decreased until the plasma concentration returned to a desirable range.[59] It was postulated that both of these clinically significant TP-DIs may be related to the effect of basiliximab on CYP activities via cytokine modulation. Interaction between IL-2 and its respective IL-2R on intestinal epithelial cells and hepatocytes may decrease the expression or activity of CYP3A4.[62] Binding of basiliximab to the IL-2R on activated T-cells may allow circulating IL-2 binding to IL-2Rs on hepatic and intestinal cells, resulting in a downregulation of CYP3A4 enzyme activity.

On the other hand, the treatment of some TPs results in a downregulation and normalization of elevated cytokine levels in the disease state through cytokine or cytokine receptor antagonism. Subsequent inhibition of cytokine-mediated downstream signaling transduction may restore the previously down-regulated CYP enzyme activity to a normal level and consequently normalize the exposure of SMDs that are CYP substrates.[52] As listed in Table 2-2, tocilizumab, an anti-IL-6R mAb for RA treatment, may have DIs based on this mechanism. In RA patients, IL-6 serum concentrations are elevated up to 50–60 pg/mL as compared to those in healthy subjects ($\sim$5 pg/mL). Tocilizumab binds specifically to both

soluble and membrane-bound IL-6 receptors (sIL-6R and mIL-6R) and inhibits IL-6-mediated signaling through blocking these receptors. This ameliorates the inflammation status.

*In vitro* data suggest that IL-6 inhibits CYP activity, and tocilizumab prevents CYP3A4 suppression by IL-6 in human hepatocytes, indicating that tocilizumab may reverse IL-6-induced suppression of CYP activities in the disease state.[60] This was demonstrated in a clinical study in RA patients in which the tocilizumab combination resulted in up to a 57% decrease in the exposure of simvastatin, a CYP3A4 probe substrate, in comparison to simvastatin alone in the same individuals. In another study, tocilizumab resulted in a 12–28% decrease in exposure of omeprazole, a CYP3A4 and CYP2C19 substrate, by comparing the exposure in the same RA patients before and after tocilizumab dosing. These observations may have clinical relevance for patients who take tocilizumab with NTR drugs for which the doses need to be individually adjusted.[60,61] Some other approved cytokine modulators, such as canakinumab (anti-IL-1β mAb),[63] golimumab (anti-TNFα mAb),[64] rilonacept (anti-IL-1R fusion protein),[65] and ustekinumab (anti-IL-12/23 mAb)[66] may also potentially normalize CYP enzymes in patients. Although no formal DI studies have been conducted for these TPs, the potential risk of TP-DIs and the need to monitor the therapeutic effects or concentrations of drugs with a NTR when given in combination with these TPs are addressed in their package inserts.

Transporters play important roles for the ADME process of SMDs. Inflammatory disease states may also affect several important drug transporters, such as *p*-glycoproteins, multidrug resistance-associated proteins, and organic anion-transporting peptides.[67] Theoretically, the risk of transporter-mediated DIs for the combinations of TPs and SMDs exists. However, to date no clinically relevant TP-DIs caused by this mechanism have been reported.

### 2.3.4 Pharmacodynamic-Based Therapeutic Protein–Drug Interactions That Lead to Toxicity without Affecting Exposures

The major objective for using combination therapy is to improve efficacy by desirable PD interactions without increasing safety concerns. As discussed earlier, PD-based TP-DIs may result in exposure changes in either the TP or the SMD given in combination, which may have clinical relevance for drugs with a NTR. In addition, PD-based TP-DIs can also lead to toxicity without affecting the exposure of the drugs in combination. PD-based TP-DIs that result in undesirable toxicity are usually documented in the labels of these TPs to guide the prescribers to avoid certain combinations. An example is the combination of anakinra and etanercept. Anakinra is a recombinant IL-1R antagonist protein that competitively inhibits the binding of IL-1 to IL-1Rs.[68] Anakinra has a molecular weight of 17.3 kDa. Etanercept is a dimeric fusion protein consisting of the extracellular ligand-binding portion of the human 75 kDa tumor necrosis factor receptor linked to the Fc portion of human IgG1.[69] Both TPs were approved for RA treatment. Because anakinra is eliminated by renal excretion and etanercept is eliminated by proteolysis with the salvage pathway of FcRn-mediated recycling, there are no overlapping clearance pathways for

them. In a phase III study in RA patients using concurrent therapy of anakinra with etanercept, the PK properties of both agents were unchanged by the combination. However, there was no significant improvement in efficacy for the combination therapy, and the risk of serious infection and neutropenia increased when compared to etanercept alone. PD-based DIs may potentially cause patients to be highly immunosuppressed and prone to infection, and an additive neutropenia effect also likely results from the use of this combination.[69,70]

Other examples are also recently reviewed.[30] For example, filgrastim, a human granulocyte colony–stimulating factor, during a period of 24 h before through 24 h after cytotoxic chemotherapy should be avoided because of the potential sensitivity of rapidly dividing myeloid cells to cytotoxic chemotherapy.[71] Aldesleukin,[72] a human recombinant IL-2 protein, may enhance the toxicity of drugs of nephrotoxic, myelotoxic, cardiotoxic, or hepatotoxic effects when given in combination. IFNα-2b[53] may cause increased myelotoxicity of myelosuppressive agents, such as zidovudine, when given in combination.

## 2.4 STRATEGIES TO ASSESS THE RISK OF THERAPEUTIC PROTEIN–DRUG INTERACTIONS IN CLINICAL DEVELOPMENT OF THERAPEUTIC PROTEINS

### 2.4.1 Challenges of Assessing Therapeutic Protein–Drug Interactions in Clinical Development

It is critical to understand the theoretical TP-DI mechanisms and build an individualized and iterative strategy to ensure the safe and effective use of TPs for combination treatment. The FDA guidance document for DI studies,[3] the European Medicines Agency (EMA) guideline on the clinical investigation of the PK characteristics of TPs,[73] and several recent review papers from the FDA highlighted the importance of evaluating TP-DIs.[1,2]

There are multiple challenges in assessing TP-DIs in clinical development of TPs, owing to the distinct PK and PD properties of TPs. Considering potential toxicity, most clinical trials involving TPs need to be conducted in the patient population instead of in healthy subjects. The PK characteristics of TPs may differ between patients and healthy subjects because of target expression levels. For immunomodulatory TPs, the CYP activity normalization by TP-cytokine-CYP interactions occurs only in patients with infection or inflammatory diseases. However, formal TP-DI studies in patients with life-threatening diseases (e.g., cancer, transplantation, severe autoimmune diseases) are rarely conducted owing to logistical constrains. Cross-over studies are difficult because of the long washout period required for TPs with long half-lives; a parallel design of two arms in a randomized study or a cross-over design for TP-DI assessment is not ethical if one of the drugs lacks efficacy when it is used alone. Concurrent medications also confound the DI evaluation of studied combinations[2,30] In addition to these challenges in clinical evaluation, *in vitro* and preclinical DI assessment strategies for TPs are very

different from SMDs and are still evolving owing to the inherent differences in metabolic pathways between TPs and SMDs.[30] Therefore, more creative and less disruptive strategies are needed to assess the risk of TP-DIs in clinical development.

### 2.4.2 Question-Based Strategy of Therapeutic Protein–Drug Interaction Assessment During Clinical Development

As summarized in Figure 2-5, a question-based TP-DI risk assessment strategy is recommended.[30] This strategy recommends both theoretical TP-DI risk assessments based on PK and PD properties of the drugs in combination (as described earlier in this chapter) and PK evaluation in phase Ib/II studies to support the theoretical assessment. If a clinically relevant TP-DI signal is detected, further assessment and confirmation might be considered in phase II/III studies. All TP-DI relevant information–including the theoretical risk of TP-DIs based on the PK and PD properties of the drugs in combination, the PK and ADME data collected at various stages in the development of combination therapy, the potential impact of TP-DIs on the safety and/or efficacy outcomes, and whether the impact warrants clinical dose adjustment and/or therapeutic drug monitoring—is documented in the package insert to provide physicians with data that allow an informed decision about whether to adjust a drug dose when administered in combination or whether to avoid a particular concomitant medication. The TP-DI risk assessments need an individualized strategy for each molecule and are iterative based on emerging data.

**FIGURE 2-5** Question-based TP-DI risk assessment strategy during TP development. CYP: cytochrome P450; NTR: narrow therapeutic range; PK: pharmacokinetic; PMR: post-marketing requirement; SMD: small molecule drug; TP: therapeutic protein; TP-DI: therapeutic protein–drug interaction.

***2.4.2.1 Theoretical Risk Assessments for Therapeutic Protein–Drug Interactions*** The PK and PD properties form the basis for the theoretical risk assessments of TP-DIs that may affect the exposure of combination drugs. To illustrate the general considerations for this theoretical assessment based on various mechanisms of TP-DIs, three tables provide examples for the combinations of a TP with a SMD or another TP in different therapeutic areas: a mAb combined with a SMD for cancer treatment (bevacizumab and irinotecan; Table 2-3), a mAb combined with a SMD for inflammatory disease treatment (tocilizumab and MTX or simvastatin; Table 2-4), and an ADC combined with a mAb for cancer treatment (T-DM1 and pertuzumab; Table 2-5).

***2.4.2.2 Evaluation of TP–DI Risk in Combination Studies by Clinical PK Assessment*** In addition to the theoretical TP-DI risk assessments, PK comparison with single-agent PK properties is recommended in phase Ib/II combination studies. These assessments are particularly important for drugs with a NTR, such as ADCs and some SMDs.

PK analysis for TP-DI assessment can be conducted by various approaches such as noncompartmental analysis (NCA) of individual patient PK profiles and population PK approaches using nonlinear mixed-effect modeling.[82,83] Among population PK approaches, the indicator approach and the simulation-based visual predictive check (VPC) approach are commonly used. With the indicator approach, a dichotomous indicator with the value of 1 or 0, corresponding to the presence or absence of the combination drug, is used as a covariate for PK parameters. The confidence intervals of the ratios from the PK parameters between the presence and absence of the interacting drug can be calculated. This approach was used to assess the impact of multiple combination agents on the PK properties of ustekinumab[84] and the impact of pertuzumab on the PK properties of T-DM1.[49] In addition, the VPC approach to PK data from combination studies based on simulations using a historical population PK model is also frequently used for cross-study PK comparisons.

Cross-arm and/or cross-study PK comparisons are often used for TP-DI assessment in phase Ib/II studies of combination therapy. For example, in a phase I combination study, MetMAb, a mAb directed against the tyrosine kinase Met, was given in combination with bevacizumab. Comparison of MetMAb in this combination with phase I single-agent MetMAb PK data using the NCA method and comparison of bevacizumab PK in this combination with historical bevacizumab PK data using the VPC method showed that no TP-DIs were observed. For a phase II study of MetMAb given in combination with erlotinib, the PK properties of MetMAb, erlotinib, and OSI-420 (a major metabolite of erlotinib) were also not altered in comparison to historical single-agent PK data using the VPC method and/or in comparison to PK parameters of the placebo plus the erlotinib arm in the same study.[85] In a phase II study of T-DM1 in combination with pertuzumab, the PK properties of pertuzumab and T-DM1-related analytes, including T-DM1, total trastuzumab, and DM1, were not changed compared to their historical single-agent data based on a cross-study comparison using both the NCA and population PK approach.[49]

**TABLE 2-3 Theoretical TP-DI Risk Assessments for the Combination of Bevacizumab and Irinotecan in Cancer Patients [13,31,74–76]**

| | | Bevacizumab | Irinotecan |
|---|---|---|---|
| PK characteristics | | Mainly cleared by nonspecific proteolytic degradation at clinically efficacious doses; linear PK property; $t_{½} = \sim 20$ days; CL = 0.2–0.3 L/day; interindividual CL variability = ~26%. | A prodrug metabolized to its active form, SN-38, by carboxyesterases; SN-38 is inactivated by UGT1A and CYP3A4; irinotecan $t_{½} = 6–12$ h; SN-38 $t_{½} = 10–20$ h. There is large interindividual PK variability for both irinotecan and its metabolite SN-38. UGT1A gene polymorphism may play a role in PK variability. |
| Risk of PK-based TP-DIs | | Low: No overlapping clearance pathways for bevacizumab and irinotecan | |
| PD characteristics | MOA | Binds to VEGF and prevents the interaction of VEGF to its receptors, leading to antiangiogenesis effect | SN-38 binds to topoisomerase I–DNA complex, preventing religation of a single-strand break induced by topoisomerase I, leading to DNA damage and cytotoxicity. |
| | TMDD | Not a major clearance route at clinically efficacious dose ranges | NA |
| | Immunogenicity | Low | NA |
| | Cytokine modulator | No | No |
| | Immuno suppressive agent | No | Yes, due to the neutropenia effect |
| | Therapeutic range | Moderate | Narrow |

(*continued*)

**TABLE 2.3** (*Continued*)

| | Bevacizumab | Irinotecan |
|---|---|---|
| Risk of PD-based TP-DIs | Risk of impact on bevacizumab exposure is low.<br>TMDD does not play a major role in total CL at clinically efficacious dose ranges.<br>Bevacizumab has relatively low immunogenicity; there is no documented impact of immunogenicity on bevacizumab CL. | Risk of impact on irinotecan exposure is low.<br>UGT1A and CYP activities are unlikely to be impacted by combination with bevacizumab |
| Risk of clinically relevant TP-DIs | Low | |

CL: clearance; CYP: cytochrome P450; MOA: mechanism of action; NA: not applicable; PD: pharmacodynamic; PK: pharmacokinetic; TMDD: target-mediated drug disposition; TP-DIs: therapeutic protein–drug interactions; UGT1A: uridine diphosphate glucuronosyltransferase 1A; VEGF: vascular endothelial growth factor.

For single-arm studies of TP-SMD combinations, a staggered dosing approach in the first treatment cycle may be applied to assess the impact of the TP on the PK properties of the SMD. In this approach, since the short half-lives of most SMDs determine a short wash-out period, a SMD may be administered alone in the first treatment cycle to allow PK assessment in the absence of the TP. In subsequent treatment cycles, the TP and the SMD are administered concurrently, and PK properties of the SMD in the presence of the TP can be assessed. This approach was used to evaluate the effect of T-DM1 on the PK properties of taxane,[36,37] the effect of bevacizumab on the PK of irinotecan,[31] and the effect of tocilizumab on the PK properties of simvastatin.[60]

A confirmatory TP-DI substudy in phase II/III might be needed when theoretical analysis and TP-DI assessment in phase Ib/II studies suggest a clinically relevant TP-DI potential. For example, it is hypothesized that tocilizumab may restore CYP activity in RA patients and therefore normalize the required doses of combination drugs of CYP substrates. To evaluate this hypothesis, a dedicated TP-DI study using simvastatin as the CYP3A4 probe substrate was conducted.[60]

In some situations, postmarketing studies to evaluate TP-DI might have to be conducted when the registration trial did not adequately address the potential for clinically relevant TP-DIs. For example, a dedicated TP-DI study for the combination of bevacizumab and irinotecan (as part of the FOLFIRI regimen combining irinotecan, fluorouracil, and leucovorin) was conducted as a postmarketing

**TABLE 2-4 Theoretical TP-DI Risk Assessments for the Combination of Tocilizumab and Other SMDs (e.g., Methotrexate or Simvastatin) in Rheumatoid Arthritis Patients [60,61,77,78]**

| | | Tocilizumab | MTX | Simvastatin |
|---|---|---|---|---|
| PK characteristics | | Nonlinear PK behavior at clinically efficacious doses; the total CL is the sum of linear and nonlinear CL; linear CL = 0.3 L/day; the concentration-dependent apparent $t_{½}$ = up to 11 days for 4 mg/kg and up to 13 days for 8 mg/kg at steady-state given on an every-4-weeks regimen. | Undergoes hepatic and intracellular metabolism to polyglutamated forms, which can be converted back to MTX by hydrolase enzymes; $t_{½}$ = 3–10 h; 80–90% of the administered dose is excreted unchanged in the urine within 24 h.<br>MTX clearance rates vary widely and are generally decreased at higher doses.<br>Not a CYP substrate | A lactone that is readily hydrolyzed *in vivo* to the corresponding β-hydroxyacid form, mediated mainly by CYP3A4, and extensively metabolized by the liver. |
| Risk of PK-based TP-DIs | | Low: No overlapping CL pathways for tocilizumab and MTX or tocilizumab and simvastatin | | |
| PD characteristics | MOA | Tocilizumab binds specifically to both soluble and membrane-bound IL-6R and inhibits IL-6-mediated signaling through these receptors; used for treatment of RA. | MTX inhibits dihydrofolic acid reductase, thus interferes with DNA synthesis, repair, and cellular replication; combination with tocilizumab is used for treatment of moderate to severe active RA in adult patients. | β-hydroxyacid is a potent inhibitor of HMG-CoA reductase, the enzyme that catalyzes the conversion of HMG-CoA to mevalonate, an early and rate-limiting step in the biosynthetic pathway for cholesterol. |
| | TMDD | Plays an important role in total CL at clinically efficacious dose ranges | NA | NA |

| Cytokine modulator | No | No | No |
| Immuno-suppressive agent | No | No | No |
| Therapeutic range | Narrow | Narrow | Wide |
| Risk of PD-based TP-DIs that impact on exposure | Low: T-DM1 and pertuzumab bind to distinct epitopes of HER2 simultaneously without steric hindrance.<br>TMDD does not play a major role in the CL of T-DM1and pertuzumab at clinically efficacious doses.<br>T-DM1and pertuzumab have low immunogenicity rates; there is no identified impact of immunogenicity on their CL; immunogenicity and CYP activities are unlikely to be affected by the combination. | | |
| Risk of clinically relevant TP-DIs | Low | | |

ADCC: antibody-dependent cellular cytotoxicity; CL: clearance; CYP: cytochrome P450; DIs: drug interactions; DM1: cytotoxic component of T-DM1; HER: human epidermal growth factor receptor; MOA: mechanism of action; NA: not available; PD: pharmacodynamic; *p*-gp: *p*-glycoprotein; PK: pharmacokinetic; T-DM1: trastuzumab emtansine; TMDD: target-mediated drug disposition; TP-DIs: therapeutic protein–drug interactions.

requirement, because a phase III study suggested a 33% increase of SN-38 (active metabolite of irinotecan) exposure and an increased incidence of grade 3 or 4 diarrhea and leukopenia in the bevacizumab and FOLFIRI combination arm compared to the FOLFIRI alone arm.[74] Whether there was a clinically relevant TP-DI potential was unknown. There are no theoretical mechanisms supporting this based on the PK and PD properties of bevacizumab and irinotecan, as assessed in Table 2-3. Unfortunately, the PK substudy in this phase III trial used limited sampling for irinotecan and thus was not definitive given irinotecan's large intersubject PK variability. The study also lacked an analysis of the uridine diphosphate glucuronosyltransferase 1A (UGT1A) genotype, which has been thought to affect the metabolic pathway of irinotecan. As a result, a controlled and fully powered clinical trial to fulfill the postmarketing requirement was conducted to investigate whether bevacizumab affected the PK properties of irinotecan and SN-38 using a staggered dosing design in cycle 1 and concurrent dosing in later cycles for bevacizumab and FOLFIRI. An exploratory analysis of UGT1A genotyping was also performed. This confirmatory study found that the PK characteristics of irinotecan and its active metabolite SN-38 were not altered by the bevacizumab combination. Pharmacogenetic analysis further confirmed that UGT1A1 gene polymorphisms were associated with variability in irinotecan and SN-38 exposure, which might explain the cross-arm exposure difference of SN-38 observed in the phase III study.[31]

## 2.5 SUMMARY

The PK properties of TPs are distinct from SMDs. TPs with a large molecular weight usually have a relatively small volume of distribution that is confined to plasma with limited penetration to the extravascular space. Unlike SMDs, most TPs are mainly catabolized via nonspecific proteolysis pathways with no involvement of CYP enzymes. FcRn-mediated recycling prolongs the half-lives of TPs that bind to FcRn, such as mAbs and some Fc fusion proteins. Some TPs may exhibit dose- and concentration-dependent PK due to a TMDD pathway. The clearance of TPs may also be affected by immunogenicity. Biliary secretion and renal excretion, the common routes of excretion for SMDs, are not common for TPs. The evolving class of ADCs belong to a more complex type of TPs made up of both a mAb and a small molecule cytotoxic agent and cleared by mechanisms relevant to both TPs and SMDs, as well as the deconjugation process determined by linker chemistry.

Owing to differences in the PK and PD properties of TPs and SMDs, the plausible mechanisms and relative risks for TP-DIs are distinct from SMD-DIs. PK-based DIs are not common for TPs, considering that the nonspecific proteolysis pathways are usually not saturable at the therapeutic concentrations of most TPs and there are usually no overlapping clearance pathways for TPs and SMDs. PD-based DIs induced by the PD effects of the combination drugs are possible for TPs. The major mechanisms of PD-based TP-DIs include modulation of immunogenicity-mediated clearance of TPs, modulation of TMDD, and modulation of CYP enzyme activity and expression through TP-cytokine-CYP interactions. To date, only modest

changes in exposure owing to TP-DIs have been observed with little relevance in the clinical setting. However, the risk of potential TP-DIs involving SMDs with a NTR may be clinically relevant. Because most drugs with a NTR are closely monitored by therapeutic drug monitoring, potential changes in exposure can typically be adjusted as needed to maintain efficacious concentrations and minimize the occurrence of adverse events. ADCs are likely to have similar mechanisms of PD-based TP-DIs, with the additional possibility of DIs between the small molecule cytotoxic component of the ADC and the combination drug.

The distinct PK and PD properties of TPs pose multiple challenges for assessing TP-DIs. Consequently, novel strategies that are different from the traditional DI assessment strategies for SMDs are required. A question-based TP-DI risk assessment approach is recommended during clinical development. This approach includes both theoretical risk assessments based on PK and PD properties of TPs and SMDs in combination and clinical PK evaluation in support of the theoretical assessment.

# DRUG INTERACTION ASSESSMENT STRATEGIES: SMALL MOLECULES VERSUS THERAPEUTIC PROTEINS

SHANNON DALLAS, CARLO SENSENHAUSER,
SOUVIK CHATTOPADHYAY, and JOSE SILVA

## 3.1 INTRODUCTION

Paramount to every small molecule drug (SMD) development program is the assessment of drug interaction (DI) liabilities involving metabolic enzymes or drug transporters. Generally, these assessments are undertaken to understand how one SMD (perpetrator) may affect the absorption, distribution, metabolism, and excretion (ADME) of another SMD (victim) and therefore determine the potential for drug–drug interactions (DDIs). The importance of DDI assessment during SMD drug development (generally in the context of pharmacokinetics-based interactions) has been highlighted in recent guidance documents and papers published by regulatory agencies worldwide, including the FDA[1–3] and the European Medicines Agency (EMA).[4] Many preclinical studies (mostly *in vitro* but also *in vivo*) have been developed over the last few decades to understand how a particular SMD may have a potential DDI risk and whether such a risk will translate into the clinic. In contrast, for therapeutic proteins (TPs), or biologics, recent concern has centered more around the ability of a TP to affect the ADME of a coadministered SMD (i.e., as a perpetrator only), although exceptions do exist. These types of TP-DI studies historically were not part of standard Biologics License Application (BLA) submissions. Table 3-1 gives a few examples of approved TPs for which DI assessment was performed and reported in the compound label.[5–10]

DDI risk assessment for a SMD often starts with well-established *in vitro* studies using human-derived models (e.g., human hepatocytes and microsomes). Inhibition (reversible, time-dependent, or mechanism-based) and induction studies of the

**TABLE 3-1 Examples of TPs That Have Drug Interaction Information Listed on the Label**

| Drug | Drug Interactions Indicated on Label |
|---|---|
| Adalimumab (Humira); TNF blocker | MTX: Adalimumab has been studied in RA patients taking concomitant MTX. Although MTX reduced the apparent adalimumab clearance, the data do not suggest the need for dose adjustment of either drug. |
| Tocilizumab (Actemra); IL-6 receptor inhibitor | MTX: Population pharmacokinetic analyses of RA patients did not detect any effect of MTX, NSAIDs, or corticosteroids on tocilizumab clearance. Other drugs for treatment of concomitant administration of a single dose of 10 mg/kg tocilizumab with 10–25 mg MTX once weekly had no clinically significant effect on MTX exposure.<br>CYP450 enzymes: *In vitro* studies showed that tocilizumab has the potential to affect expression of multiple CYP enzymes, including CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. Its effects on CYP2C8 or transporters is unknown. *In vivo* studies with omeprazole (metabolized by CYP2C19 and CYP3A4) and simvastatin (metabolized by CYP3A4) showed up to a 28% and 57% decrease, respectively, in exposure 1 week after a single dose of tocilizumab. The effect of tocilizumab on CYP enzymes may be clinically relevant for CYP450 substrates with a narrow therapeutic index, for whichthe dose is individually adjusted. |
| Trastuzumab (Herceptin); HER2/neu receptor antagonist | Chemotherapeutic drugs: In a study involving metastatic breast cancer patients, the mean serum trough concentration of trastuzumab (4 mg/kg initial dose of trastuzumab followed by 2 mg/kg weekly) was consistently elevated approximately 1.5-fold when administered in combination with paclitaxel (175 mg/m$^2$ over 3 hours every 21 days for at least six cycles) as compared to trough concentrations of trastuzumab when administered in combination with an anthracycline and cyclophosphamide (doxorubicin 60 mg/m$^2$ or epirubicin 75 mg/m$^2$ plus 600 mg/m$^2$ cyclophosphamide every 21 days for six cycles). In other pharmacokinetic studies, where trastuzumab was administered in combination with paclitaxel, docetaxel, or doxorubicin, trastuzumab did not alter the plasma concentrations of these chemotherapeutic agents or the metabolites that were analyzed.<br>In another drug interaction study involving gastric cancer patients, the pharmacokinetics of cisplatin (80 mg/m$^2$ on day 1), capecitabine (1000 mg/m$^2$ orally twice a day on days 1–14), and their metabolites were not altered when administered in combination with trastuzumab (initial dose of 8 mg/kg administered on day 1 prior to chemotherapy, followed by 6 mg/kg every 21 days until disease progression). |

**TABLE 3.1** (*Continued*)

| Drug | Drug Interactions Indicated on Label |
|---|---|
| Belatacept (Nulojix); fusion protein (Fc portion of human IgG1 linked to CTLA-4 | MMF: In a pharmacokinetic study the plasma concentrations of MPA were measured in 41 patients who received fixed MMF doses of 500–1500 mg twice daily with either 5 mg/kg of belatacept or cyclosporine. The mean dose-normalized MPA $C_{max}$ and $AUC_{0-12}$ were approximately 20% and 40% higher, respectively, with belatacept coadministration than with cyclosporine coadministration. |
| Peginterferon α-2a (Pegasys) | Theophylline: Treatment with peginterferon α-2a once weekly for 4 weeks in healthy subjects was associated with an inhibition of CYP1A2 and a 25% increase in theophylline AUC.<br>Methadone: In a pharmacokinetic study of HCV patients concomitantly receiving methadone, treatment with peginterferon α-2a once weekly for 4 weeks was associated with methadone levels that were 10–15% higher than at baseline. The clinical significance of this finding is unknown. |
| Interferon γ-1b (Actimmune) | CYP450s: Preclinical studies in rodents using species-specific interferon-γ have demonstrated a decrease in hepatic microsomal CYP450 concentrations. This could potentially lead to a depression of the hepatic metabolism of certain drugs that use this degradative pathway. |

CYP450: cytochrome P450; HCV: hepatitis C virus; HER2: human epidermal growth receptor 2; IgG: immunoglobulin G; IL-6: interleukin 6; MPA: mycophenolic acid; MMF: mycophenolate mofetil; MTX: methotrexate; NSAID: nonsteroidal anti-inflammatory drug; RA: rheumatoid arthritis; TNF: tumor necrosis factor.

major cytochrome P450s, inhibition studies of non-CYP pathways (e.g., uridine 5′-diphospho-glucuronosyltransferases), and metabolic enzyme phenotyping are well established and run routinely. Although the liver is often the first organ examined, studies can be expanded to other organ systems (e.g., kidney or intestine) depending on a compound's characteristics (e.g., physiochemical properties or pharmacokinetics profile), mode and site of action, molecular target, clearance mechanisms, and clinical population. The potential role of drug transporters in compound disposition (as substrates, inhibitors, inducers, or suppressors) is assessed by numerous *in vitro* assays, which are also readily available. However, the relevance of individual transporters for potential DDIs is currently less well understood compared to metabolic enzymes. The *in vitro* kinetic data generated from these various assays (e.g., kinetic constants) can then be used to predict DDI risk clinically, using mechanistic modeling and simulation, such as physiologically based pharmacokinetic (PBPK) modeling. If a potential risk is identified, clinical DDI studies are conducted to characterize the magnitude of the interaction and predict how this might affect the safety and use of a potential new drug entity with comedications. PBPK modeling can provide simulations broadly across multiple populations, including special populations, such as pediatrics, geriatrics, and in renal or hepatic insufficiency. In addition, PBPK modeling is emerging as a viable alternative to actual

clinical DDI trials, in some cases. When submitting a new drug for approval, these studies would be a standard part of the drug application process. More recently, the possibility of some TPs, such as monoclonal antibodies and fusion proteins, to cause clinically relevant DIs (either directly or indirectly) has received renewed attention. The FDA and EMA have included language in their drug development guidance documents about how to assess the risk of a TP-DI.[3,11]

This chapter is not intended to give an expansive and detailed review of all of the methods and assays used for DDI assessment during SMD development because this has already been accomplished by others in the field.[12] Rather, general concepts and methods will be discussed for some of the typical assays undertaken in SMD development, including whether these methods can be, should be, or already have been applied in the context of TP-DI assessments. This chapter serves as a starting point for understanding the complexity and difficulties in assessing TP-DIs. The reader will be guided to other chapters within this volume that discuss these concepts more extensively and to specific case studies when appropriate.

## 3.2 DRUG-METABOLIZING ENZYMES

### 3.2.1 Cytochrome P450 Enzymes

Metabolic clearance generally involves biotransformation reactions catalyzed by a wide variety of drug-metabolizing enzymes (DME). Biotransformations are typically classified as either phase I or phase II reactions. Generally, phase I metabolic reactions aim at inactivating a drug through the introduction of a more polar functional group (—OH, —COOH, —$NH_2$, —SH, etc.) by oxidation, dealkylation, reduction, hydrolysis, cyclization, etc. Various classes of enzymes can be involved in phase I metabolism: cytochrome P450 (CYP), flavin-containing monooxygenases, amidases, carboxylesterases, and epoxide hydrolases. Because as much as 60% of currently marketed drugs are metabolized by one or several CYP isoforms,[13,14] focus has been directed at DDIs involving CYPs, although similar kinetic approaches can be applied to other classes of phase I enzymes.

Phase II metabolism, on the other hand, leads to formation of conjugates of the initial substrate—either the parent compound through direct conjugation or a phase I metabolite through indirect conjugation via uridine 5′-diphospho-glucuronosyltransferases (UGTs), glutathione-*S*-transferases, sulfotransferases, *N*-acetyltransferases, and methyltransferases—resulting in higher molecular weight compounds with improved water solubility, which increases renal or biliary clearance.[15,16] Phase II metabolism also provides a mechanism to inactivate potentially toxic electrophilic products of phase I metabolism. Although clinically relevant DDIs involving phase II metabolism have not been reported as frequently as with the CYPs, bioactivation through conjugation can occur, for instance through the formation of acyl glucuronides or thioesters resulting from conjugation of carboxylic acid moieties. Their inherent electrophilicity, deriving from the spontaneous tendency to undergo hydrolysis and intramolecular rearrangements (e.g., acyl migration) makes them

susceptible to protein adduct formation, and they have been implicated in observed adverse effects.[17] One notable example of phase II metabolism-derived DDI is the inactivation of CYP2C8 by gemfibrozil glucuronide, which will be briefly discussed later in the chapter.

The CYP superfamily of enzymes is widespread throughout nature and is present in all types of living organisms, ranging from bacteria to plants and animals. Of the more than 11,000 CYP proteins identified to date,[18] only a few dozen isoforms are of interest from a drug metabolism perspective and in terms of potential for adverse DDIs. Their nomenclature is based on the extent of amino acid sequence homology. Only the CYP1, CYP2, and CYP3 subfamilies are known to be primarily involved in the metabolism and bioactivation of pharmaceutical SMDs.[19] CYPs are proteins that contain a heme molecule that is noncovalently bound in the active site. The heme binds molecular oxygen and allows the catalytic cycle to carry out a biotransformation reaction by receiving protons and electrons from a cofactor, NADPH, and a closely associated oxidoreductase protein, producing 1 mol of water as a byproduct. CYP proteins, together with other phase I and some phase II enzymes are situated in the lipid bilayer of the endoplasmic reticulum, where they can efficiently catalyze the conversion of lipophilic xenobiotics to their oxidized metabolites and conjugates.

Other DMEs are found in the cytosolic region of the cell. Most DMEs share the characteristic of having broad substrate selectivity, being able to accommodate structurally diverse substrates in the active sites, albeit at the expense of turnover rates, which are typically much lower than those observed for enzymes involved in endogenous cell regulation and biosynthesis. This lack of substrate specificity, leading to the possibility of the same substrate being metabolized by different CYPs or different CYPs metabolizing the same substrate to produce different metabolites at different turnover rates, can ultimately lead to observed adverse DDIs. Characterization of the kinetic parameters of these reactions from *in vitro* assays can provide a valuable predictive tool during SMD development when incorporated with current modeling and simulation methods, such as PBPK.

### 3.2.2 Inhibition

A drug binding to a CYP enzyme typically displays hyperbolic saturation (Michaelis-Menten) kinetics, meaning that as the concentration of substrate is increased the first-order rate of product formation (often referred to as rate of substrate turnover or velocity), reaches a maximal rate of efficiency ($V_{max}$). Under these conditions, the enzyme present is completely in the enzyme–substrate (ES) complex form and is therefore saturated. Rates higher than $V_{max}$ are not possible; therefore, increasing substrate concentration beyond a certain point will not have any effect on substrate turnover, and zero-order kinetics are attained. In cases that deviate from classical Michaelis-Menten kinetics, such as substrate inhibition or autoactivation, changes in $V_{max}$ as substrate concentration increases can be observed). In addition, the substrate concentration that yields 50% of the maximal turnover rate, the Michaelis-Menten constant ($K_m$) represents the affinity of a substrate for the enzyme catalyzing its metabolic conversion. The ratio $V_{max}/K_m$, or

intrinsic clearance ($CL_{int}$), expressed in units of volume over time, provides a measure of the overall enzymatic capacity for a specific substrate. When this basic kinetic model is modified by the introduction of a second compound, which can either compete with the substrate for the active site of the same enzyme or act as an effector molecule, binding to an allosteric site of the enzyme, the rate of substrate turnover may be either inhibited or activated. In these cases, metabolic conversion of the substrate, the victim drug, will be driven not only by its concentration but also by the concentration of the perpetrator drug and the relative affinities of the two compounds to the enzyme. If a victim drug does not have alternate routes of elimination, inhibition of the enzyme will affect the exposure and pharmacokinetic profile more significantly. In addition to the *in vitro* determination of the kinetic parameters of inhibition, consideration of the fraction metabolized ($f_m$) by the inhibited enzyme and by other CYP and non-CYP enzymes, contributions by the gut to first-pass metabolism, the extent of biliary and renal clearance of the unchanged drug, and plasma protein binding all have to be taken into account as inputs in the prediction of changes in exposure (AUC) of a victim drug resulting from coadministration of a perpetrator drug.

In SMD development, several models, ranging from whole cell (hepatocytes) to subcellular fractions (microsomes; S9) and single enzyme expression systems, are routinely used in assays designed to evaluate the effect of a drug on CYP activity. For the determination of kinetic parameters, however, microsomes are the system of choice[20] because they provide kinetic data independent of other cellular and transport mechanisms present in whole cell systems. It is also widely recognized that Michaelis-Menten kinetic models require certain assumptions based on the steady-state, rapid equilibrium approach: (a) the amount of enzyme is negligible compared to the amount of substrate; (b) all of the enzyme can be accounted for as either free enzyme (E) or ES and enzyme-inhibitor (EI) complexes, all of which are in equilibrium for the duration of the assay; and (c) the amount of product formed is minimal compared to the substrate concentration, so the reaction remains within the linear range and substrate depletion is not rate limiting and does not affect assay kinetics. Consistent with these assumptions, microsomal assays should be run at low protein concentrations (typically $<0.5$ mg/mL, provided product formation is sufficiently detectable and linear within the time frame it is being measured), with constant conditions (cofactor, pH, temperature, and ionic strength) throughout the reaction.[20] Recent advances in methodologies, highlighted in the newest FDA DDI guidance[3] have included the identification and standardization of CYP-specific probe substrates and inhibitors, which specifically address the need to accurately monitor the activity of a CYP isoform without significant contributions from other isoforms. The widespread availability of metabolite reference standards and their deuterated analogs also allow for more accurate and sensitive quantification methods using current high-performance liquid chromatography tandem mass spectrometry (HPLC/MS/MS) analytical techniques.

***3.2.2.1 Reversible Inhibition*** Reversible inhibition results from noncovalent binding of an inhibitor to the enzyme in such a way that access of a substrate to the

**FIGURE 3-1** Enzyme-substrate-inhibitor interactions and kinetic equilibria for the three major models of reversible inhibition. E: enzyme; ES: enzyme–substrate; I: inhibitor; P: product; S: substrate. (Reprinted with permission from Rong-Huay Juang, National Taiwan University.[70])

active site is prevented, either by directly competing for the active site, or by causing conformational changes to the enzyme (caused by allosteric effects) that affect the efficiency (turnover rate) of the reaction. The inhibitor could be a molecule that is structurally similar to the substrate but that is not necessarily chemically modified by the enzyme it inhibits or is modified at a substantially lower rate. It could also be a molecule that binds to a site different from the active site (allosteric or effector site), causing changes that prevent the substrate from binding. Therefore, from a kinetics standpoint, reversible inhibition models vary based on whether the inhibitor binds only to the free enzyme or also to the ES complex and whether product can be formed from the ES complex only or also from the enzyme-substrate-inhibitor (ESI) complex, albeit possibly at a reduced rate. Briefly, these models are summarized as follows (Figure 3-1):

- *Competitive inhibition.* Both substrate and inhibitor compete for the active site of the enzyme, and the equilibrium can be driven one way or the other by increasing the concentration of either compounds. As such, the $V_{max}$ is not affected, although more substrate is needed to compensate for the presence of the inhibitor and therefore apparent $K_m$ increases. Competitive inhibition can also be observed as a result of binding to an allosteric site on the enzyme, provided that it binds only to the free enzyme.
- *Mixed inhibition.* The inhibitor can bind to both E and the ES complex, to an allosteric site different from the binding site, causing conformational changes and thus reducing the efficiency of the enzyme and the affinity of the substrate for the enzyme. However, the equilibrium can be partially driven by increases in substrate concentration; therefore, apparent $K_m$ increases.

- *Noncompetitive inhibition.* A subset of mixed inhibition, the inhibitor binds to a different enzyme site but does not affect the affinity of the substrate binding to the active site, although it cannot be chemically modified by the enzyme. It reduces the efficiency of the enzyme, therefore affecting the maximal turnover rate ($V_{max}$ decreases), but because the affinity of the substrate for the enzyme does not change, apparent $K_m$ is not affected.
- *Uncompetitive inhibition.* The least common model with CYP enzymes, in which the inhibitor binds only to the ES complex, reducing its efficiency but increasing the apparent affinity of the substrate for the enzyme. In this case, both $V_{max}$ and $K_m$ decrease.

Experimental assessment of the potential to inhibit a specific enzyme typically begins by determining if incubation of the test compound in the presence of an established probe substrate causes loss of enzymatic activity as represented by a decrease in formation of the metabolite of the probe substrate. If the appropriate range of test compound concentrations is selected and, most important, if the probe substrate is incubated at a concentration that is equal or below its determined $K_m$ value, the $IC_{50}$ value of the inhibitor–that is, the concentration of inhibitor that lowers enzymatic basal activity levels by 50% can be determined. $IC_{50}$ values provide an approximate estimation of the potential of a compound to act as an inhibitor, but they are extrinsic constants and depend on experimental conditions and substrate concentrations.

The EI complex dissociation constant, $K_i$, is an intrinsic kinetic parameter and more appropriate in estimating potential DDIs. It can be estimated from determined $IC_{50}$ values, provided that substrate concentration is equal to its $K_m$ value and that the mode of inhibition is consistent with either the competitive model (in which case $IC_{50} = 2 \times K_i$) or the noncompetitive model ($IC_{50} = K_i$).[21] Experimentally, it is determined by incubating several substrate concentrations (preferably bracketing the substrate $K_m$ value) in the presence of a range of inhibitor concentrations (preferably bracketing 0.2 to 5 times the expected $K_i$ value)[22] and plotting the enzyme velocities ($v$, turnover rates) as functions of inhibitor ([I]) and substrate ([S]) concentrations. Graphical representations of the data, such as Michaelis-Menten ($v$ versus [S]), Lineweaver-Burk ($1/v$ versus 1/[S]), Dixon ($1/v$ versus [I]) or Eadie-Hofstee plots ($v$ versus $v$/[S]), can also provide insight on the appropriate inhibition mechanism (Figure 3-2).

More complex models have been extensively observed with enzymes exhibiting kinetic profiles that deviate from the traditional Michaelis-Menten model. CYP3A4, the most abundant and primary isoform involved in the metabolism of xenobiotics, has been shown to commonly exhibit non-Michaelis-Menten kinetics, due to homotropic cooperative effects resulting from the presence of multiple binding sites[23,24] or to flexible binding sites that can accommodate multiple substrates simultaneously.[25] These models can be represented as nonhyperbolic kinetic profiles—for example, in the case of substrate inhibition, as with midazolam, velocity decreases at higher substrate concentrations after an initial hyperbolic phase. In the case of autoactivation, as with testosterone, a sigmoidal profile of velocity as a function of

**FIGURE 3-2** Enzyme inhibition models. The different reversible inhibition models (competitive, noncompetitive, mixed, and uncompetitive) can be differentiated by using Eadie-Hofstee plots. The *y*-intercept corresponds to $V_{max}$, the slope corresponds to $-K_m$ and the *x*-intercept corresponds to $V_{max}/K_m$, or the intrinsic clearance ($CL_{int}$). Inh: inhibition.

substrate concentration is observed.[26,27] It is common practice, therefore, to screen interactions between a potential CYP3A4 inhibitor with more than one CYP3A4-specific substrate, to assess binding to the different domains (midazolam, testosterone, and nifedipine are used as the prototypical substrates).[28]

As inhibition constants provide an indication whether exposure of an enzyme to a perpetrator drug may have a concomitant effect on the pharmacokinetic profile of a victim drug, their value is essential in estimating the potential for *in vivo* DDI by a SMD. Therapeutic proteins, though unlikely to have similar kinetic intracellular interactions with CYP enzymes, could trigger different indirect mechanisms affecting the basal activity levels of an enzyme, prompting as a result, similar pharmacokinetic interactions (see section 3.2.4).

***3.2.2.2 Time-Dependent Inhibition*** When an inhibitor or substrate is converted enzymatically to a reactive species, it may inactivate the enzyme in a time- and concentration-dependent fashion.[29] Recently, emphasis has been placed on differentiating between time-dependent inhibition (TDI) and a particular subset defined as mechanism-based inactivation (MBI). Several mechanisms can trigger TDI of an enzyme. They can be typically identified after a preincubation period in the presence of a metabolizing system and are therefore NADPH dependent. Some of these mechanisms may not necessarily require bioactivation and may result, for instance, from the formation of species with a higher inhibitory affinity than the parent compound. A compound causing MBI, on the other hand, is one that binds catalytically to the target enzyme and is metabolically converted to a reactive species. This reactive metabolite can then bind covalently and irreversibly to a moiety of the active site of the apoprotein or in a quasi-irreversible fashion, if a reactive species forms a metabolic intermediate complex (MIC) with the heme group of the CYP enzyme. For example, alkyl and aromatic amines can be bioactivated to form a nitroso intermediate species, which coordinates tightly with the heme but in a noncovalent way. This interaction can be reversed almost completely by oxidizing agents, such as potassium ferricyanide, as in the case with troleandomycin.[30]

Greater concern from a DDI perspective is generated when these reactive intermediates interact covalently or quasi-irreversibly to CYP3A4. Often, DDIs triggered by these irreversible mechanisms can be more unfavorable compared to DDIs owing to reversible inhibition because the inactivated enzyme has to be replaced by

newly synthesized protein (*de novo* synthesis). As in the case with reversible inhibition, the potency of inactivation can be assessed by determining the kinetic parameters of inactivation, $k_{inact}$, defined as the maximal rate of inactivation and $K_I$, indicating the potency or affinity of the inactivator for the enzyme, defined as the concentration that causes 50% of the maximal rate of inactivation. An additional parameter provides a measure of efficiency of the inactivation and is defined as the number of inactivator (substrate) molecules that are turned over per molecule of enzyme that is inactivated; it is called the apparent partition ratio (APR).[31–33]

APR screens can be carried out easily and effectively by incubating the test compound at serially diluted concentrations, with and without NADPH, in a primary reaction mixture. After 60 min, an aliquot of the reaction mixture is transferred to a secondary reaction that contains an excess of CYP-specific probe substrate and additional NADPH, to assay for residual enzymatic activity. A dilution in the transfer step, typically 10- to 20-fold and the excess of probe substrate, ensure that any observed loss in residual activity is the result of inactivation of the enzyme during the primary incubation and not due to possible reversible interactions with the unchanged inactivator or any generated metabolite transferred to the secondary reaction mixture. The residual activity data are normalized to the maximal activity observed in the absence of inactivator and are plotted as a function of the molar ratio of inactivator to CYP enzyme. Any separation between the curves corresponding to the +NADPH and −NADPH primary incubation samples indicate that the observed loss of activity appears to be time, concentration, and NADPH dependent, identifying a TDI and possible MBI. The APR value can be determined from the linear range of the activity curve as a function of molar ratio, which can be extrapolated to the intercept of the $x$-axis, as shown by the interaction of mifepristone a known 3A4 MBI (Figure 3-3). In contrast, ketoconazole, a strong reversible inhibitor exhibits the opposite behavior (greater loss of activity without NADPH), as the potent reversible inhibition interacts with the probe substrate.

Although microsomes have traditionally been the system of choice for TDI screens and kinetic determinations, hepatocytes have recently gained increasing value as a better predictive model that incorporates mechanisms and transport not present with microsomes. A study of several known CYP3A4 inactivators resulted in generally lower potencies, either lower affinities or lower rates of inactivation than those typically calculated from microsomal data. However the hepatocyte-derived lower potencies appeared to correlate better with observed clinical data when simulated with PBPK.[34]

Determination of the kinetic parameters of inactivation, $k_{inact}$ and $K_I$, is an extension of the APR assay. Again, serially diluted test compound concentrations are incubated in a primary reaction containing NADPH, but activity is assayed at several time points. The apparent rates of inactivation generated from the semilog time course can be plotted as a function of the inactivator to yield the customary Michaelis-Menten-like hyperbolic plot, from which the kinetic parameters of inactivation can be determined by nonlinear regression (Figure 3-4). The concept of screening for potential TDIs or MBIs has become pivotal in SMD development, as evidenced also by the postmarket withdrawals of several previously approved drugs found to

**FIGURE 3-3** APR curves for mifepristone, a known CYP3A4 TDI, and ketoconazole, a potent CYP3A4 reversible inhibitor. Serially diluted concentrations of either compound were incubated with an NADPH (solid lines) or without an NADPH (dashed lines) regenerating system for 60min. Residual CYP3A4 activity was assayed by transferring an aliquot of each initial incubation to secondary incubations containing midazolam (CYP3A4 probe substrate) and NADPH. Residual activity was normalized to the activity in a vehicle control and was graphed as a function of inactivator to CYP3A4 molar ratio. The concentration- and NADPH-dependent loss of activity was consistent with a TDI. Ketoconazole, as a potent but reversible inhibitor, does not cause NADPH-dependent loss of activity and exhibits stronger loss of activity in the absence of NADPH. APR: apparent partition ratio; TDI: time-dependent inhibitor.

**FIGURE 3-4** Inactivation time course of CYP3A4 by mifepristone and hyperbolic: plot of apparent first-order rates of inactivation as a function of mifepristone concentrations. Mifepristone was serially diluted (0.01 to 30 μM) and incubated in the presence of an NADPH-regenerating system. Aliquots were removed for each concentration level at specific time points (0, 5, 15, 30, 45, 60 and 90 min) and transferred to a secondary reaction mixture containing 10 μM midazolam ($5\times K_m$) to assay for residual activity. Samples were normalized for each time point to vehicle incubates and plotted as the natural log of residual activity as a function of time. Apparent first-order rates of inactivation were derived from the slopes of the decay curve for each concentration and were plotted as a function of inactivator concentration to yield a hyperbolic inactivation plot. The maximal rate of inactivation, $k_{\text{inact}}$ ($=0.035\,\text{min}^{-1}$), was determined from the zero-order kinetic plateau of the hyperbolic curve and the inactivation constant, $K_{\text{I}}$ ($=0.74\,\mu\text{M}$) was calculated as the inactivator concentration yielding 50% of the maximal inactivation rate.

be TDIs and the cause of unexpected drug-induced liver injuries and idiosyncratic toxicities.[35,36] Because of the different nature of the interactions between TPs and DMEs, TDI in the classical sense is unlikely, although interactions affecting signaling pathways leading to time-dependent effects in the expression or activity levels of DMEs are certainly possible. In these cases, investigating the TP as a potential perpetrator would assess the likelihood of potential DDIs.

***3.2.2.3 Inhibition of Non-CYP Enzymes*** A number of additional classes of phase I enzymes play significant roles in drug metabolism. Recurrence of DDI is less frequent, and as a result, enzymes such as the flavin-containing monooxygenase (FMOs), epoxide hydrolases, and carboxylesterases have not been the source of consistent scrutiny. Their significant role in drug design is to provide alternate routes of elimination of drugs to mitigate the possibilities of CYP-related DDI. Phase II enzymes also do not tend to be involved in clinically relevant DDI. Glucuronidation and other phase II reactions tend to have higher capacity, faster turnover rates than phase I reactions and consequently do not contribute to marked changes in AUC and other PK parameters. Several significant exceptions should however be noted: the UGT1A1-catalyzed glucuronidation of bilirubin, the rate-limiting step in the clearance of bilirubin,[37] and the UGT2B7-catalyzed conversion of gemfibrozil to the acyl glucuronide conjugate, which was found to be a more potent reversible inhibitor of CYP2C8 than the parent drug.[38] Subsequently, the gemfibrozil acyl glucuronide conjugate was also identified as a strong time-dependent inhibitor of the same isoform through an uncommon CYP2C8-catalyzed oxidation of the conjugated form (phase I hydroxylation following a phase II conjugation), generating a reactive intermediate (possibly a substituted hydroquinone), which can then covalently bind to and inactivate the CYP enzyme.[39] As with the CYPs, DDIs arising from direct interactions of TPs with non-CYP enzymes such as UGTs are unlikely. However, indirect interactions via transcriptional or post-transcriptional regulation cannot be ruled excluded.

### 3.2.3 Reaction Phenotyping

Reaction phenotyping in SMD development is designed to establish if a drug candidate has the potential to be a victim drug and consequently have a higher *in vivo* DDI risk. Determining the CYP isoforms, non-CYP enzymes, and phase II reaction pathways that are involved as routes of metabolic clearance of a new molecular entity will allow the identification of potential metabolic liabilities. Phenotyping studies should therefore be designed to provide a complete scheme of the biotransformation landscape of a drug candidate. Commercially available single recombinant enzyme expression systems from bacterial, insect, or mammalian cells have facilitated determining these metabolic pathways. These assays can be routinely used to confirm involvement of specific enzymes in the catalytic conversion of a SMD. Studies are usually designed in a sequential approach as follows:

- General metabolic stability is initially determined in either microsomal or intact cell systems.

- An initial review of the major metabolites detected can subsequently trigger the selection of the possible biotransformation pathways to be investigated.
- Determination of the kinetic parameters ($K_m$, $V_{max}$) of the major metabolic pathways is carried out in microsomes by monitoring rates of metabolite formation at varying substrate concentrations. Establishing the rates of conversion and the affinity for a specific pathway will provide a better understanding of the potential for saturation of an enzyme and possible DDI consequences. This should be done in relation to the expected systemic concentration levels based on anticipated dosing regimens.
- Contributions of a specific pathway to the overall metabolic clearance are then investigated by simulated DDI scenarios; varying levels of known chemical inhibitors of the targeted pathway or inhibitory monoclonal antibodies of the specific enzyme are incubated with the substrate to monitor and quantify relative changes in the metabolic profile.

Reaction phenotyping as applied to enzyme substrates in SMD development is presumably not applicable to TP as the likelihood of similar enzyme–substrate interactions is remote. But it can be used as an important tool for defining the risk of TP-DI, with the protein acting as a potential perpetrator.

### 3.2.4 Induction and Suppression

Induction potential of compounds toward CYP1A2, 2B6, and 3A4 via the aryl hydrocarbon (AhR), constitutive androstane (CAR), and pregnane X (PXR) nuclear receptors (NRs), respectively, is routinely determined during SMD development. Significant CYP induction can result in therapeutic failure from clinical exposure of a compound outside the therapeutic window, if the respective enzymes are responsible for a significant portion of its overall metabolism and clearance. Similarly, exposure of a comedication that is also metabolized by the induced enzymes can be decreased significantly in a similar manner. Over repeated doses, autoinduction can occur by which the exposure of the drugs will decrease over time and result in nonlinear PK.[40] In this case, subtherapeutic concentrations of the drugs may result, which can lead to reduced efficacy at the site of target—that is, therapeutic failure. In addition, if metabolism via the induced CYP enzyme results in toxic or pharmacologically active compounds being produced, exaggerated pharmacological effects may be seen resulting in direct and/or indirect toxicity.

Multiple well-characterized models are available for examining CYP induction, either in a discovery screening setting (e.g., NR assays, hepatocyte cells lines) or later during drug development (e.g., human hepatocytes). A complete list of *in vitro* and *in vivo* methods used to study CYP induction, along with respective advantages and disadvantages is available.[41,42] Nuclear receptor luminescence assays such as PXR and AhR are well suited for a discovery setting because they can be easily automated and provide a first readout on potential enzyme induction. In general, there appears to be good agreement between $EC_{50}$ values generated in the nuclear receptor assays compared to those generated in human hepatocytes.[41] Use of cryopreserved or freshly

isolated human hepatocytes plated on simple multiwell plates (2D cultures) is considered the gold standard *in vitro* assay for examining potential induction of CYP enzymes via nuclear receptors.[3] It is well known that upon isolation and culture, basal levels of CYP enzymes decrease dramatically in hepatocytes owing to rapid cell dedifferentiation. Therefore these models are well suited for detecting a potential increase in enzyme expression after incubation for a predetermined time frame. Typically, hepatocytes are plated on collagen-coated microwell plates, allowed to attach, and then cultured for hours to several days before treatment with known inducers or test compounds for an additional 48–72 h. In this simple system, the cells cannot survive beyond 5 days. Use of a matrigel or collagen overlay to generate sandwich cultures has been used to extend the life of hepatocyte cultures for an additional 1–2 days. At the end of the dosing period, gene expression and enzyme activities can be assessed.[43] Kinetic constants (i.e., $EC_{50}$, $E_{max}$) generated from these studies can then be used for PBPK modeling to predict clinical effects. Although the *in vitro* to *in vivo* correlation (IVIVC) using primary hepatocytes has been relatively good, the absolute fold induction tends to be overpredicted by the *in vitro* assay.[41]

In addition to primary hepatocytes, hepatocyte-derived cell lines such as Fa2N-4, HepG2, BC2, and HepRG have been used previously for CYP induction or other mechanistic studies.[44,45] Ease of use, unlimited availability, and ability for manipulation via SiRNA or transfection has made these models attractive. However, at this time they are not considered a suitable replacement for primary human hepatocyte models because they either are not fully equivalent to primary hepatocytes in terms of enzyme expression or have not been fully validated.[46,47] For example, the Fa2N-4 cell line does not express functional levels of the CAR receptor and therefore cannot be used to assess CYP2B6.[48] Induction of other metabolic enzymes has been studied during SMD development, but more as a case-by-case basis. UGT1A1 induction can be examined in 2D hepatocytes alongside the CYPs. However, in this system induction of other UGT isoforms is generally modest.

Preclinical *in vivo* models (e.g., rodents, dogs, primates) to understand CYP induction risk are generally used in a more mechanistic manner during SMD development, for example, to understand nonlinear PK or toxicity observed during chronic dose studies. Even for SMD, extrapolating enzyme changes in preclinical species to humans is difficult due to species differences in enzyme expression and activity.[49] Recent advances in transgenic technologies have led to the availability of humanized liver mice, which may hold promise for bridging the gap between *in vitro* human and clinical studies, however this remains to be proven. Chapter 6 provides an overview of the potential use of animal models for predicting DDI by TP. Induction potential of metabolic enzymes in the liver by TP (*in vitro* or *in vivo*) has not been previously reported. It is interesting that exposure of nonhepatic cell types, including peripheral blood mononuclear and brain parenchymal cells to proinflammatory cytokines, does result in CYP induction[50,51] The relevance of induction of metabolic enzymes in these cells, which have little metabolic capability, is currently unknown.

Generally, suppression of CYP enzyme expression (gene or activity) has not been of particular importance during SMD development. Suppression of CYP enzymes by biologics such as immunomodulators (e.g., interferon-γ; IFN-γ)

appears to be a more likely liability. The concern for enzyme suppression in the context of TP is as follows: a patient with an inflammatory disease has increased circulatory cytokines, such as interleukin 6 (IL-6) and tumor necrosis factor α (TNF-α). These cytokines have the potential capacity to decrease CYP enzyme levels through global suppression of NRs via interaction with a shared heterodimer subunit RXR and the master regulator NF-κB.[52,53] In these patients doses of narrow therapeutic index compounds such as theophylline are titrated according to the patient's metabolic capacity to achieve effective and safe drug exposures. If a patient is then treated with an anti-IL-6 or anti-TNF-α antibody, a reversal of the reduced basal CYP activity levels might occur, resulting in therapeutic failure of the coadministered SMD, via increased drug metabolism and decreased exposure and/or increased toxicity (see Chapter 11 on Tocilizumab example). In contrast, for TPs that are direct immunomodulators (e.g., IFN-γ), suppression of CYP levels might result in decreased clearance of coadministered drugs, which could result in increased drug exposure and toxicity.

Because the mechanism of CYP suppression by cytokines is likely via NRs, 2D hepatocyte cultures have been used by several groups to understand how particular cytokines, either alone or in combination, may affect the expression and/or activity of the major CYPs.[54–57] However, studies on the suppression of non-CYP enzymes by cytokines in these same models are currently lacking. The advantages, disadvantages, and open questions regarding this methodology as well as other *in vitro* methods in the context of TP-DI are addressed in detail in Chapters 5 and 13. At this time, the predictability of simple hepatocyte assays has been questioned by multiple groups.[55,58] This lack of confidence in predictability likely explains the current regulatory opinion regarding *in vitro* assessments of TP-DI (see Chapter 10). Nonetheless, further understanding of the molecular mechanisms underlying cytokine-mediated CYP suppression may help bridge the gap of IVIVC for TP-DI. For example, the suppression of CYP3A4 by IL-6 is known to occur in a time-dependent manner based on both mRNA and activity measurements[57]. Furthermore, interaction of IL-6 with its cell surface receptor (a required step to start the cascade toward CYP suppression) results in what one could consider a quasi-irreversible activation of molecular pathways. Once activated, a subsequent invagination and recycling of the receptor occurs. Based on these observations, Kenny[59] has suggested modeling the suppression of CYP mRNA using kinetic methodology similar to SMD TDI assessments (also time dependent and irreversible). By measuring the suppression of mRNA over time and using multiple concentrations of IL-6, $K_I$, and $k_{inact}$ constants can be determined and used for subsequent PBPK modeling of TP-DI risk for comedications. General strategies around model-based methods and TP-DIs are described in Chapter 4. While still early, these types of analyses show promise.

## 3.3 TRANSPORTERS

In general, compounds can cross biological membranes in several different ways: through paracellular or transcellular routes or via transporter proteins embedded in

**FIGURE 3-5** Routes of translocation for pharmaceutical compounds through cellular membranes. 1. Lipid soluble compounds can permeate through the epithelium by simple passive diffusion (transcellular route). 2. Small molecular weight compounds such as $CO_2$ can permeate through the tight junctions (TG) between cells (paracellular route). 3. Facilitative transport (e.g., uptake of amino acids) occurs via a transport carrier down the concentration gradient of the solute. Transport can also occur via a carrier but against the concentration gradient of the solute. 4. In the case of efflux transporters such as P-glycoprotein, ATP-hydrolysis is the driving force for this transport. 5. Uptake carriers, such as the organic anion, and organic cation transporters can also transport substances against a concentration gradient. The driving force depends on the particular transporter but can be pH dependent or electrogenic, for example. 6. Some hormones are transported through the epithelium via receptor-mediated transcytosis. The ligand binds to a cell surface receptor, which causes an invagination in the membrane. This invagination is internalized and carried to the opposite membrane, where the ligand is then released (Reprinted with permission from Ref. 62.)

the membrane (Figure 3-5). From a pharmaceutical perspective, active efflux and uptake transporters (routes 4 and 5 in the figure) are considered most relevant with respect to SMD. Two superfamilies of transporters are particularly important: the solute carrier or SLC family and the ATP binding cassette or ABC superfamily. Within these families several dozen drug transporters have been identified, and their characteristics (substrates, inhibitors, clinical relevance) have been reviewed in detail elsewhere.[60] Recently seven of these drug transporters have been highlighted to have particular clinical relevance for DDI and have been described in publications by the FDA or consortia, such as the International Drug Transporter (ITC) consortium.[3,61] These transporters include P-glycoprotein (P-gp), breast cancer resistance protein (BCRP), organic anion transporter polypeptide 1B1 and 1B3

(OATP1B1/1B3), organic cation transporter 2 (OCT2), and organic anion transporters 1 and 3 (OAT1/3).

### 3.3.1 Substrate and Inhibitor Studies

Drug transporters are found in multiple organs throughout the body and play an important role in absorption, distribution, and overall drug clearance (metabolism and excretion).[62] Multiple organ-specific *in vitro* transporter models exist that are of varying value for understanding compound transport characteristics. These include 2D suspension hepatocytes (liver uptake), 2D hepatocyte overlay, or "sandwich" cultures (liver efflux), brain endothelial cell models (brain efflux/influx), and Caco-2 cells (intestinal permeability). These cellular systems are easy to use, readily available, contain multiple tissue-relevant transporters (along with metabolizing enzymes in some cases), and can be useful in determining whether a potential DDI liability may exist. For example, uptake of a compound into hepatocytes, which is both saturable and inhibited by statins (e.g., rosuvastatin), may indicate an OATP1B1 liability. This potential DDI risk can then be followed up mechanistically using single transporter transfected/transduced cell lines. Madin-Darby canine kidney (MDCKII), human embryonic kidney (HEK), and Chinese hamster ovary (CHO) cells are most commonly used. These polarized cells can be grown on permeable inserts to study compound flux (from the apical-to-basal and basal-to-apical directions), grown on impermeable plates to access apically located transporters only, or turned into inside-out vesicles. The latter model is useful for compounds that are poorly permeable, such as conjugated drug metabolites. As with the CYPs, these *in vitro* systems can be used to generate kinetic values for DDI risk assessment using PBPK modeling and simulation. Michaelis-Menten constants such as $K_m$ and $J_{\max}$ describe the affinity and maximal rate, respectively, of a compound for a particular transporter. Inhibition studies that generate $IC_{50}$ values can assess the risk of inhibiting transport resulting in a DDI, either as a victim or a perpetrator. Compared to the CYPs, the prediction of clinically relevant DDI involving transporters is still in its infancy. Generally, the ability of a compound to interact with a given drug transporter (as a substrate or inhibitor) is based largely on physiochemical properties (log P, MW, solubility, etc.). Therefore, it is unlikely that large TPs such as monocloncal antibodies or fusion proteins will be direct substrates or inhibitors of classical drug transporters. However, drug-transporter function can also be affected indirectly through perturbations of lipid bilayer integrity and composition, alterations in required transporter-driving forces (e.g. $Na^+/K^+$ ATPase, pH gradient) or alterations in proper membrane trafficking.[63,64] Whether these mechanisms will be of importance in the context of TP-DI is yet to be determined.

### 3.3.2 Induction and Suppression

The clinical significance of induction of transporters, in contrast to CYPs, is poorly understood, and difficult to replicate *in vitro*. Although regulation of transporters occurs via nuclear receptors such as PXR and CAR, the duplicative cross-talk that

occurs between these NRs and others such as the farnesoid X receptor and AhR is still yet to be fully explored. At present, there are no clinical examples of a TP that has caused an increase in transporter expression or function directly. However, similar to the CYPs, there is a theoretical concern that suppression of transporter expression may occur, particularly for immunosuppressant compounds. The consequence of this suppression depends largely on the characteristics of the victim SMD. For example, for an anionic drug cleared exclusively via the kidney, a suppression of OAT1 or OAT3 could decrease renal excretion and therefore increase exposure and potential drug toxicity.[65] On the other hand, for a cationic compound, this suppression may be of no consequence. Unlike the CYPs, for which the major focus of possible suppression has been centered mainly on the liver, in the case of transporters changes in function or expression in multiple organs may affect the overall ADME of a coadministered compound, including the gut (absorption), kidney (elimination), and brain (central nervous system distribution).

Thus far, work around drug transporter suppression in the liver via cytokines has been undertaken in preclinical species such as rodents[66,67] and, more recently, in primary human hepatocytes using methodologies similar to those used for CYPs.[68,69] Known species differences in transporter expression and affinities may complicate interpretation of rodent generated data. In addition, sandwich hepatocyte cultures will be more appropriate for examining canalicular transporters, such as P-gp and BCRP, because the correct orientation of those transporters is lost in simple 2D hepatocyte cultures. Because the underlying mechanism for transporter suppression may be similar to that of the CYPs, presumably one could apply similar $K_I/k_{inact}$-type PBPK analyses for TP-DI prediction. However, the inherent complexity of drug transporter regulation and the propensity for multifaceted interactions involving metabolism/transporter interplay might make these seemingly simplistic models difficult to interpret. A significant amount of research is certainly needed in this area.

## 3.4 CONCLUSION

In the SMD arena, a robust toolbox of *in vitro* and preclinical models have been developed to derisk many DDI liabilities and decrease the number of clinical DDI studies required for a given compound. Nonetheless, even for small molecules the predictability of some DDI assessments (e.g., transporter induction and transporter-metabolism interplay) remains difficult owing to a lack of well-validated models and a poor understanding of the molecular mechanisms. Although it seems logical to apply decades of knowledge and experience from the small molecule world to TP-DI assessment, it is not surprising that the inherent differences between these two types of compounds have made this challenging. As our understanding of the underlying mechanisms driving TP-mediated interactions increases and as technology platforms evolve and improve (both *in silico* and *in vitro*), accurate prediction of clinically relevant TP-DIs will, we hope, become possible. In the meantime, there is much work to do to make this a practical reality.

# MODEL-INDEPENDENT AND MODEL-BASED METHODS TO ASSESS DRUG–DRUG INTERACTIONS FOR THERAPEUTIC PROTEINS

DI WU and JEFFREY S. BARRETT

## 4.1 INTRODUCTION

Therapeutic proteins (TPs) are playing a greater role in pharmacotherapy due to their high potency and mechanism of action. The main therapeutic protein classes include monoclonal antibodies, interferons, interleukins, hormones such as growth hormone and insulin, colony-stimulating factors, and blood clotting factors. TP therapies have been applied in a variety of disease areas, such as oncology, autoimmune disorders, infectious diseases, and hormone deficiencies.

The value of the global market for TPs was estimated at $93 billion in 2010, with a compound annual growth rate (CAGR) of 16.4% between 2002 and 2010. The market is forecasted to grow at a CAGR of 6.2% between 2010 and 2017, to reach $141.5 billion in 2017.[1] Therefore, TPs are expected to occupy a significant portion of the commercial portfolios of many large pharmaceutical companies. Likewise, their presence on drug formularies and in the marketplace in general necessitates a greater understanding for both the lay and the scientific communities.

By the year 2050, 34.6% of the world population will be aged more than 65 years.[2] Polypharmacy is frequently encountered when treating senior patients, resulting in a high drug–drug interaction (DDI) potential. Unexpected DDIs can lead to reduced efficacy or toxicity. Because the approval of human recombinant insulin as the first biologic by the FDA in 1982,[3] TPs have been used clinically. With the increasing use of TPs, TP-drug interactions (TP-DIs) are more prevalent, and public awareness has increased.

## 4.2 TP-DIs

Because TP-DI research is still a new and emerging area, limited data are available from the drug development of TPs. The interactions of TPs with small molecule drugs (SMDs) and other TPs[4] are likewise based on sparse experience. The basic mechanisms behind TP-DIs certainly need to be further investigated.

### 4.2.1 Therapeutic Target and Window

Monoclonal antibodies (mAbs) are one of the most important classes of TPs. They have been approved in a variety of indications, but most are developed to treat cancer and autoimmune diseases. A distinguishing feature of the class is that mAbs can specifically bind to therapeutic targets (i.e., target cells or proteins). Binding may then stimulate a patient's immune system to attack those targets. The therapeutic targets can be identified as either soluble or cellular. The mAbs targeting cellular antigens exhibit complex and nonlinear PK, whereas mAbs that bind to soluble antigens usually have linear PK over a wide dose range with clearance usually assessed as dose independent. In most cases, the clearance of cellular antigen-binding mAbs decreases with increasing dose in a low dose range, stabilizing to a constant value after the target-mediated, nonlinear elimination pathway is saturated. Thus it is important to select appropriate dose(s) for a DDI study of a mAb that binds to cellular antigen.[3]

Similar to small molecules, TPs with a wide therapeutic range would not present a safety concern in regard to DDI. A safety margin of 10 or greater is empirically considered a wide therapeutic window for a TP.[3]

## 4.3 *IN VITRO* AND *IN VIVO* APPROACHES FOR EVALUATING TP-DI

*In vitro* and *in vivo* approaches for evaluating DDI for TPs can be grouped into model-independent and model-based methods. The strategy to design and conduct a TP-DI study should be based on the clearance mechanisms and biological mechanisms of action.[5] Multiple doses of small molecules are sometimes required for testing TP-DIs because small molecules usually have much shorter half-lives than those of TPs.[6] Compared with small molecule DDI evaluation, a scientifically based and operationally feasible strategy and design should be incorporated into TP-DI exploration and investigation. Selection of interacting drugs should be based on clinical probability of concomitant utilization, the therapeutic range of the small molecule drug, and the pharmacokinetic (PK) and pharmacodynamic (PD) characteristics of the drugs.

The FDA published draft guidance for DDIs for industry, including a section on TP-DI, in February 2012.[7] This draft guidance provides instructions for *in vitro* and *in vivo* studies on TP-DIs. However, case-by-case-based TP-DI studies are commonly designed and evaluated. Risk-based strategies for TP-DI evaluation are extensively executed in the pharmaceutical industry in the United States.[3,5]

Model-independent methods include *in vitro* screening, dedicated DDI studies, and "cocktail" DDI studies. Model-based methods include population PK/PD-based DDI studies.

### 4.3.1 *In Vitro* Screening

Currently, human-cultured hepatocyte assay is considered as the most commonly used preclinical approach to assess the effects of TPs on CYP enzymes and transporters using clinically relevant concentrations of TPs or physiologically relevant concentration of cytokine/cytokine modulators.[3,8,9] This method allows for direct assessment of the effect of TPs on CYP isozymes and drug transporters. It has been suggested that preclinical evaluations should not be required if a TP drug candidate is one of the cytokines or cytokine modulators with reported effects on cytochrome P450 (CYP) isozymes and drug transporters,[10] or if it is a mAb directed against one of those cytokines and/or their receptors. This class of TP drug candidates should be directly assessed in a clinical DDI study.[8,10] However, if the TP drug candidate is one of the cytokines or cytokine modulators with no reported effects on CYP isozymes and transporters,[10] or it is a mAb directed against one of those cytokines and/or their receptors, using a human cultured hepatocyte assay is recommended for testing the TP-DI propensity with a minimum of three different hepatocyte donors.[3,8] No preclinical studies are generally required if a TP drug candidate is not cytokine related.

An *in vitro* cytokine release assay has been used to evaluate cytokine release potentials from a TP drug candidate. Because healthy human blood is applied, the assay is limited to the safety assessment of TP immunomodulatory capacity and results from the assay are difficult to translate to the *in vivo* setting where TP targets are located in the body outside the circulation.[8]

The *in vitro* approach needs to be optimized further to ensure both qualitative and quantitative evaluation of TP-DIs. At this point, all results from *in vitro* screening should be viewed qualitatively. Furthermore, *in vitro–in vivo* correlation for TP-DIs has not been established and needs further investigation. In addition, *in silico* translational prediction built on a good understanding of the basic mechanisms underlying TP-DIs is still under development.[5]

A good attempt has been made to predict the human PK of a mAb exhibiting target-mediated drug disposition (TMDD).[11] System parameters were obtained from *in vitro* experiments or literature, such as binding affinity ($k_{on}$ and $k_{off}$), internalization of the drug–target complex ($k_{int}$), target degradation rate ($k_{deg}$), and target abundance ($R_o$), incorporated into a TMDD model and developed in a population-based approach to predict human PK using monkey PK data as well. The modeling and simulation results showed that prediction of human PK was within one- to two-fold of the observed data from a phase I study. This well-designed study illustrates the excellent combination of *in vitro* experimental methods with population-based modeling to predict clinical data in a clinically relevant range.

Animal models are rarely used in the assessment of TP-DIs at present. One limitation of animal models used in small molecule drug development is the fact of

highly species-specific immune tolerance. Because tolerance is highly species specific and good correlations between animals and humans are hardly established, animal models have so far been rarely used in drug development of TPs and evaluation of TP-DIs.[12]

### 4.3.2 Clinical DDI Investigations

Clinical DDI studies are recommended to be conducted in patients, not healthy subjects, for several reasons. Firstly, PK differences of TPs may exist between healthy subjects and patients, and secondly, there is the potential of toxicity of some TPs and small molecule drugs, making it unethical to conduct the studies in healthy subjects. More important, CYP isozyme levels may have been down-regulated in chronic inflammatory diseases, such as rheumatoid arthritis and some infectious diseases. If TP-DIs are mediated through CYP isozymes, anticytokine effects of TPs would normalize the down-regulated CYP enzyme activities or expressions and thereby alter the clearance of coadministered small molecule drugs.[5,10]

***4.3.2.1 Dedicated Clinical DDI Studies*** A dedicated clinical DDI study is often applied for the reliable evaluation of TP-DIs. Common study designs for dedicated clinical DDI studies include parallel, crossover (TPs with short half-lives), and single-sequence crossover (TPs with long half-lives; small molecule drug PK during run-in period compared with small molecule drug PK after single or multiple doses of TP).[8,13]

In a pharmacokinetic study of repeated subcutaneous and intravenous administration of golimumab in patients with rheumatoid arthritis, the effect of concomitant administration of methotrexate (MTX) was examined in an open-label, randomized study.[14] A parallel design was used in the clinical DDI study of golimumab. Golimumab pharmacokinetics was described using noncompartmental analysis (NCA). In the group receiving subcutaneous golimumab administration, the geometric means of golimumab CL/F in patients cotreated with MTX and patients not cotreated with MTX were 13.9 and 21.2 mL/d/kg, respectively. Compared with the patients not cotreated with MTX, the mean $C_{max}$ and $AUC_{0-28d}$ at steady state were 24% and 37% higher, respectively, in patients cotreated with MTX. In this example, NCA is used efficiently to evaluate TP-DI by comparing $C_{max}$, AUC, and CL/F in the two scenarios. NCA requires a sufficient number of samples collected especially in the terminal phase and around $C_{max}$.

Another dedicated DDI study investigated the effects of concomitant tocilizumab on MTX PK in patients with rheumatoid arthritis. The study showed that the 90% CIs for mean ratios in systemic exposure ($AUC_{last}$ and $C_{max}$) of a combination therapy of tocilizumab and MTX and a monotherapy of either MTX or its metabolite 7-hydroxymethotrexate were all within the 80–125% bounds. C-reactive protein, a PD marker, returned to baseline within a week after tocilizumab injection. Therefore, tocilizumab and MTX can be administered concurrently without any concern of DDI in this population.[15]

In addition, a cross-study comparison approach can be used in TP-DI evaluations involving PK data comparison between healthy subjects and patients or historical data. Basiliximab clearance was significantly lower when co-treated with azathioprine ($29 \pm 14$ mL/h) or mycophenolate mofetil ($18 \pm 8$ mL/h) when compared with its established clearance of $37 \pm 15$ mL/h. Population-based nonlinear mixed-effect models were used to derive all the PK parameters used in the comparison.[16] Another example of using historical data for TP-DI study comparisons is a study of trastuzumab emtansine and pertuzumab.[17] However, results generated from such comparisons should be confirmed in specific DDI studies in the same patient population.[4] As another approach, a crossover design can be used to evaluate the effect of a coadministered drug on a TP. TP PK after cotreatment with another TP or a small molecule drug in patients can be compared with TP PK obtained in a first-in-patient TP monotherapy study. The most rigorous approach for assessing TP-DI is to implement a within-patient comparison. Careful interpretation should be given on the possible interference of antidrug antibodies resulting from the crossover design.[8]

***4.3.2.2 Cocktail Clinical DDI Study*** The "cocktail" clinical DDI study is designed to screen the effect of a TP on multiple CYP isozymes via the use of corresponding prototypical CYP probes. Compared to administration of only a single probe in a dedicated DDI study, multiple CYP probes are simultaneously administered in a cocktail DDI study to identify several potential CYP isoenzymes involved in TP-DIs. The cocktail used should be safe and use validated probe drugs for specific enzymes. Ideally, only one enzyme should be involved in the elimination of the probe drug. But if the second enzyme is metabolizing the same probe drug, its contribution to the total clearance of the very probe drug should be less than 10%. The probe drugs used should be validated by the applicant or published in the literature. In cocktail DDI studies, doses used for probe drugs should be validated both individually and in combination to ensure no interference in the pharmacokinetic interaction(s) among them. In any DDI studies, dose and duration of the investigational drug should be sufficient to estimate the maximum inhibition and/or induction achieved at a clinically relevant dose.[7,18,19] Though cocktail DDI studies are sometimes perceived as less optimal than studies testing DDIs individually, they are an efficient approach to gather more information in a single study.[3] Principles and different designs of cocktail DDI studies have been reviewed.[20,21] (see also Chapter 7).

Few TP cocktail DDI studies have been published at present. It is still questionable if the design and experimental conditions used for TPs would be the same or similar as those used for a small-molecule cocktail study. One example in cocktail TP-DI studies has been reported in a study assessing the effect of IFNα-2b on CYP isozymes.[22] High-dose IFNα-2b (HDI) is used as a standard adjuvant therapy for the treatment of high-risk melanoma. The potential effect of HDI on CYP isozymes was evaluated in 17 patients with high-risk melanoma. A Pittsburgh cocktail was used in this study with a single-sequence crossover design. A CYP isozyme activity was measured using the index derived by quantifying a selectively isozyme probe drug (and/or its metabolite) which were given at certain points of time. The results

showed that HDI had substantial effects on some CYP isozymes (e.g., CYP1A2 by 60% decrease) and no effect on other isozymes (e.g., CYP2E1). A significant association has been found between the degree of CYP inhibition and the occurrence of side effects in HDI therapy, indicating a pathophysiological basis of the HDI-induced toxicity.

TP-DI studies are preferentially conducted early in the drug development process (e.g., during phase Ib/II) because of the relatively small study size needed. In addition, early assessment of DDIs by rigorous scientific design can provide safety information and development strategies to ensure the success of late-stage drug development.

### 4.3.3 Model-Based Method: Population PK/PD–based DDI Study

Population PK/PD modeling plays a significant role in drug development of TPs. Population PK/PD modeling can be a screening tool to assess and identify TP-DIs initially, which can then be confirmed in subsequent formal DDI studies if deemed necessary. It can also be used to explore whether a TP is a perpetrator or a victim for a TP-DI if both TP and small molecule drug are sampled simultaneously.[3]

The structure and mechanism of action of mAbs are closely linked to the systemic exposure and pharmacological response of mAbs. PK/PD modeling on mAbs has been used to elucidate the mechanisms of action and to optimize dose regimens.[23–25]

Both NCA and population PK approaches have their advantages and limitations. Population PK modeling aims to develop models to describe drug disposition and obtain insights on mechanisms of drug actions when linked with PD as well as assess covariate effects. NCA allows the estimation of terminal half-lives and exposure statistics. Population PK modeling can incorporate data more efficiently (e.g., sparse or rich data as well as data from different occasions) and provide uncertainty measures for the estimated PK parameters. Certainly NCA requires less effort to perform and generate results in a much faster manner. However, population PK modeling approach provides advantages over NCA when sparse samples are present and covariate effects or mechanisms are needed to explore in the target population.

In the DDI study of MTX and infliximab (IFX) in ankylosing spondylitis patients, population PK modeling was used to estimate population parameters and evaluate the MTX effect on final parameters.[26] A parallel design was used in this investigation. MTX cotreatment did not influence any population PK parameter when examined as a covariate in the established IFX population model. Furthermore, no significant difference of $AUC_{18}$ and AUE (area under the curve of PD marker) was observed between the IFX and the IFX + MTX groups.

## 4.4 BIOANALYTICAL CONSIDERATIONS

Most TP concentrations are quantified by ligand-binding assays (LBAs) in designated biological matrices. Specificity and selectivity issues are the bioanalytical

challenges when using LBA. Specificity and selectivity of an assay for a TP of interest should be assessed during method validation of LBA.[8,27] LBA capture and detection reagents are crucial to determine assay specificity for free, partially bound, fully bound, or total antibodies as well as specificity for free and total targets. Existing metabolites and inactive species in the biological matrices might interfere with the determination of the TP concentrations and lead to overestimation of the assay results. It is critical to understand the mechanisms of the assays for a better interpretation of study results in regard to data reliability and limitations. The design of LBA bioanalytical methods (free or total concentrations) should be conducted according to the aims of the applications.[28]

In a recent study of identifying the discrepancy between enzyme-linking immunosorbent assay (ELISA) and liquid chromatography tandem mass spectrometry (LC-MS/MS) assay results of a PEGylated scaffold protein in postdose monkey plasma samples, the presence of antidrug antibodies specific to the engineered antigen-binding region of this scaffold protein affected the ability of drug to bind to the target antigen used in the ELISA assay.[29] Thus the ELISA method measured only the active circulating PEGylated scaffold protein, whereas the LC-MS/MS method measured the total circulating drug. LC-MS/MS results exerted an approximately 1.53-fold higher total exposure ($AUC_{tot}$) than the ELISA results. The bioanalysis of TPs can be compromised by drug-binding endogenous components or ADAs in the incurred samples. Therefore, good understanding of the principles of different bioanalytical methods is essential to select the appropriate approaches for specific TPs.

## 4.5 CONCLUSION

Individualized and iterative approaches for evaluation of TP-DIs should clearly be implemented in the TP drug development program. With a thorough understanding of the mechanisms of actions of TPs, TP-DI studies can be scientifically assessed, designed, and conducted. Thus a risk-based strategy is expected to guide the appropriate design and execution of TP-DIs. The risk-based strategy takes in account an evaluation of therapeutic target (cellular or soluble antigens), therapeutic window (wide or narrow), and mechanisms of DDI (*in vitro* and *in vivo*) of a particular TP of interest. Once the risk factors are evaluated and identified, the appropriate approach can be selected to design the DDI study (parallel, single-sequence crossover, or crossover) and analyze the data (NCA and/or population PK-based modeling).[3]

Model-independent and model-dependent approaches are the two main methods used to evaluate DDI between a TP and a small-molecule drug as well as between two TPs, and to predict DDI in different scenarios within model defined populations and scopes. Further investigations into the likely mechanisms involved in TP-based DDIs are needed. A critical next step is the early identification of DDI potential for TPs as well as a more granular understanding of those likely to be clinically relevant.

# UTILITY OF *IN VITRO* METHODS IN DRUG–DRUG INTERACTION ASSESSMENT AND PREDICTION FOR THERAPEUTIC BIOLOGICS

THERESA NGUYEN, NARENDRA KISHNANI, and RAYMOND EVERS

## 5.1 INTRODUCTION

Therapeutic proteins (TPs) are increasingly being coadministered with small molecule (SM) drugs and/or other biologics such as monoclonal antibodies (mAbs). Historically, interactions between TPs and SMs have not been considered very likely because mechanisms involved in the disposition of both modalities are fundamentally different. In the case of SMs, various drug-metabolizing enzymes and transporters expressed primarily in the intestine, liver, and kidney are involved in absorption, distribution, and elimination. For mAb, non-ligand and ligand-mediated clearance pathways are involved. In addition, binding to the neonatal Fc receptor (FcRn) functions as a salvage pathway that protects IgG molecules from lysosome-mediated degradation. In general, these differences will make it less likely that drug–drug interactions (DDIs) will occur between TPs and SMs. However, the situation may be different for TPs involved in pathways that modulate the immune system because it has been demonstrated that increased cytokine exposure can result in reduced levels of cytochrome P450 (CYP) enzymes and drug transporters.

Theoretically, the effects of cytokines on CYPs can therefore mediate DDIs between TPs and SMs when immunomodulating biologics (e.g., cytokines and cytokine modulators) are used in the treatment of cancer, infections, or inflammation. The scenarios that could lead to suppression or desuppression of enzymes have been outlined by Morgan[1] (Figure 5-1): When an individual, previously stabilized on a SM drug regimen becomes afflicted with an infection or inflammatory

**FIGURE 5-1 Suppression and desuppression of CYP450 enzymes owing to cytokines and cytokine modulators.** (a) An individual previously stabilized on a small molecule drug regimen becomes afflicted with an infection or inflammatory response. As a result, the associated elevated levels of proinflammatory cytokines (e.g., tumor necrosis factor α, interleukin 1β, and interferon γ) may decrease levels of drug-metabolizing enzymes and potentially lead to a decline in drug clearance and supratherapeutic small molecule drug exposure. (b) In contrast, in patients with a preexisting inflammatory disease accompanied with increased levels of the proinflammatory cytokines, treatment with an anticytokine drug could result in normalization of previously suppressed drug-metabolizing enzymes levels and potentially increase drug clearance, leading to subtherapeutic exposure of small molecule drugs.

response, the associated elevated levels of proinflammatory cytokines (e.g., tumor necrosis factor α, interleukin 1β, interleukin 6, and interferon γ) may decrease the levels of drug-metabolizing enzymes and potentially lead to a decline in drug clearance and supratherapeutic SM drug exposure.[1] In contrast, in patients with a preexisting inflammatory disease accompanied with increased levels of the proinflammatory cytokines, treatment with an anticytokine drug could result in normalization of previously suppressed drug-metabolizing enzyme levels and potentially increase of drug clearance, leading to subtherapeutic exposure of SM drugs.

A classic example of metabolizing enzyme suppression owing to infection or inflammation is the administration of theophylline (a CYP1A2 substrate) to patients

with influenza, resulting in toxic accumulation of drug as a result of reduced levels of CYP1A2.[2] Reduced clearance (10–50%) of theophylline was also found in patients infected with the hepatitis B or C virus who were treated with interferon α (IFN-α) or IFN-β.[3] Recently, an example of desuppression of CYP3A4 activity was described in patients with rheumatoid arthritis (RA) treated with the anti-IL-6 receptor mAb tocilizumab.[4] It was observed that administration of simvastatin to RA patients resulted in higher plasma drug concentrations than those reported in healthy subjects. Conversely, simvastatin exposure approached normal levels after treatment with tocilizumab. Because clearance by CYP3A4 contributes substantially to the clearance of simvastatin, treatment with tocilizumab may have normalized the inflammation-mediated reduction in CYP3A4 activity.

Currently, drug–drug interactions reported for TPs as perpetrators and SM drugs as victims in general have been small, and a generalization of the extent of interactions is not feasible at this point owing to the limited availability of clinical data. Excellent reviews on the clinical examples available have been published[5–8] and therefore will not be discussed further in this chapter.

Due to the long half-life of commonly used TPs such as mAbs and the difficulty in many cases to recruit patients for trial enrollment, the conduct of well-designed clinical interaction studies is generally costly and difficult. Therefore, there is a strong desire to develop *in vitro* approaches allowing predictions of whether significant interactions between TPs and SMs are likely. Goals of this chapter are to provide an overview of the current literature on the effects of proinflammatory cytokines on absorption, distribution, metabolism, and excretion (ADME) genes *in vitro* and to provide a perspective on the current challenges and future opportunities to establish improved *in vitro* systems.

## 5.2 MECHANISMS INVOLVED IN SUPPRESSION OF DRUG-METABOLIZING ENZYMES

The data presented in Table 5-1 suggest variability in the effect of individual cytokines on CYP enzymes in hepatocytes. For example, interleukin 6 (IL-6) and IFN in general caused *pan*-suppression across most CYP isoforms analyzed. In contrast, IL-1 appears to affect only a subset of the analyzed CYP isoforms. This suggests that there may be more than one mechanism in hepatocytes that could contribute to cytokine-mediated modulation of CYP expression levels. Potentially, this could have implications for DDI potential because CYP regulation may be affected by different types of inflammatory disease.[1] The general mechanisms by which cytokines interact with metabolic enzymes and transporters are illustrated in Figure 5-2. Several reviews on the molecular mechanisms identified to date that could lead to suppression of drug-metabolizing enzymes and transporters are available.[1,24–27] The major mechanisms resulting in gene suppression are summarized below.

The transcriptional activation of CYP3A4 as illustrated in Figure 5-3 is known to be mediated by the nuclear receptor pregnane X receptor (PXR), a ligand-dependent transcription factor.[28] PXR forms a complex with its obligate partner retinoid X

**FIGURE 5-2 Proposed general mechanisms of cytokine regulation of metabolic enzymes and transporters.** At the transcriptional level, cytokines can modulate gene expression of metabolic enzymes and transporters through interaction with various nuclear transcription factors—such as NF-kB, PXR, and CAR. At the post-transcriptional level, decreased enzyme and transporter proteins may be the result of reduction in mRNA stability owing to oxidative stress, suppression of protein translation, and/or increase in enzyme degradation due to elevated levels of NO associated with inflammation. Dotted lines: multiple intermediate steps may be involved; solid lines: a more direct effect. CAR: constitutive androstane receptor; IL: interleukin; NO: nitric oxide; PXR: pregnane X receptor; TNF: tumor necrosis factor.

receptor (RXR), and this complex in turn binds to the consensus DNA sequence elements in target genes (Figure 5-3a). PXR can be activated after binding to agonists such as rifampicin and play an important role in the induction of CYP gene transcription such as CYP3A4. In addition, it has been demonstrated that, at least in mice, PXR also plays a role in the basal transcription of Cyp3a.[29] Gu and coworkers[19] showed in human primary hepatocytes that TNF-α (2 ng/mL, 24 h) inhibited rifampicin-induced CYP3A4 mRNA levels by more than 50%. It was suggested that suppression of CYP3A4 may be mediated through the interference of the PXR-RXR-regulated pathway, and not by reduction in PXR gene transcription, because mRNA levels were unchanged in human primary hepatocytes. The researchers showed that activation of NF-κB in HepG2 cells was directly responsible for the suppression of the PXR-regulated gene expression and the presence of SRIκBα, an NF-κB super repressor, was able to reverse the suppression. In addition, it was demonstrated that NF-κB directly interacts with RXR to create a steric hindrance and disrupts the interaction of the RXR-PXR heterodimer to the PXR response element. The result is a suppression of gene transcription (Figure 5-3b).

The constitutive androstane receptor (CAR) is also involved in the transcriptional control of a number of drug-metabolizing enzymes and transporters, such as

**FIGURE 5-3 Regulation of CYP3A4 by pregnane X receptor (PXR) and its obligate partner retinoid X receptor (RXR).** (a) Upon heterodimerization of PXR with RXR and co-activators, the complex binds to the consensus PXR response elements in target genes, leading to gene transcription. (b) The presence of proinflammatory cytokines will activate NF-κB, which in turn will bind to RXR and disrupt interaction of the RXR-PXR heterodimer to the PXR response element. The result is a suppression of gene transcription. It is hypothesized that the same mechanism could result in suppression of CAR-mediated transcription activity (CAR: constitutive androstane).

CYP3A4, CYP2B6, and UGT1A1.[30] Similar to PXR, CAR-mediated gene transcription also requires the formation of the CAR-RXR heterodimer complex. It is hypothesized that the same mechanism by which NF-κB interacts with the PXR-RXR complex (Figure 5-3b) may also explain the interaction of NF-κB with the CAR-RXR complex to suppress of CAR-mediated transcription activity. In addition, NF-κB may also regulate CAR-mediated transcription of drug-metabolizing enzymes and transporters through interaction with the glucocorticoid receptor (GR). Assenat and coworkers[11] demonstrated that IL-1β activation of NF-κB can inhibit the transcriptional activation of GR, resulting in diminished CAR mRNA expression and leading to reduced CAR-mediated gene transcription (i.e., CYP3A4). A similar mechanism has been proposed for the downregulation of the aryl hydrocarbon receptor (AhR), a nuclear receptor involved in the regulation of CYP1A transcription after treatment with lipopolysaccharide (LPS) or TNF-α.[31]

IFN-α activation of gene transcription is mediated through the Janus kinase–signal transducer and activator of transcription (JAK-STAT) pathway. In the hepatoma cell line HepG2, it was demonstrated that transfection with STAT1 downregulated transcription of a CYP3A4 promoter containing reporter construct, whereas overexpression of a dominant negative STAT1 partially reversed the down-regulated CYP3A4 expression.[21] Based on these results, it was concluded that components of the JAK-STAT pathway are either directly or indirectly involved in the downregulation of CYP3A4 by IFN-α. These results are in contrast to earlier data in rodents

which suggested that IFN regulation of CYP3A4 is through the induction of xanthine oxidase, which can lead to elevated reactive oxygen intermediates and result in CYP3A4 protein degradation.[32] Subsequent work, however, indicated that this would not be a plausible mechanism and that downregulation is more likely to occur at the transcriptional level.[33]

Reactive oxygen species can also mediate transcriptional regulation of drug transporters by activating NF-κB. Ros and coworkers[34] noted that TNF-α induction of Mdr1b can be facilitated through various pathways, including NF-κB and p53, transcription factors for which binding sites in the Mdr1b promoter have been identified.[35,36] The authors observed that in both rat primary hepatocytes and hepatoma H-4-II-E cells, a time-dependent stimulation of the Mdr1b expression by TNF-α was detectable. Furthermore, in rat hepatoma H-4-II-E cells expressing dominant negative p53 (rendering nonfunctional proteins), TNF-α upregulation of Mdr1b was unaffected, suggesting that induction was independent of functional p53. In addition, in transient transfection assays, Ros' group also showed that Mdr1b upregulation correlated with activation of the promoter and that mutation of the NF-κB site in the Mdr1b promoter prevented its induction by TNF-α.[34]

Collectively, these results from both rat primary hepatocytes and hepatoma H-4-II-E cells suggest that induction of the rat Mdr1b gene by TNF-α is a result of activated NF-κB signaling (by elevated reactive oxygen species) and independent of p53.

Although the majority of evidence suggests that cytokines exert their effect on drug-metabolizing enzymes at the transcriptional level, work by Morgan's group has provided evidence that post-transcriptional mechanisms can be involved as well.[1] For instance, in human and rat hepatocytes, the presence of either LPS or IL-1 has been shown to induce nitric oxide (NO) synthase, resulting in elevated NO levels, which can lead to CYP2B protein degradation.[23,37] Lee and coworkers demonstrated that in rat hepatocytes IL-1 can stimulate NO-dependent CYP2B1 degradation via increased ubiquitination and subsequent proteasome-mediated protein degradation.[37] Donato and coworkers demonstrated that in human primary hepatocytes within 24 h of IFN-γ treatment (300 U/mL), an increase in NO release (200% over untreated control) was observed in parallel with the inhibition of CYP1A2 activity and protein levels.[20] Similarly, after the addition of *S*-nitroso-*N*-acetylpenicillamine (SNAP), which spontaneously generates NO in the cell culture medium, the concentration of nitrite increased and a corresponding concentration-dependent inhibition of CYP1A2 activity was observed; the highest inhibition (70% compared to untreated cells) reached at 2 mM SNAP. Conversely, the addition of up to 1 mM of $N^G$-monomethyl-L-arginine, a competitive inhibitor of NO biosynthesis, lead to reduction in IFN-γ-induced NO formation, and partial reversal of IFN-γ inhibition of basal and 3-methylcholanthrene-induced CYP1A2 activity.

## 5.3 *IN VITRO* ASSAYS

The present landscape of available *in vitro* methodologies for examining the interactions between cytokines and cytokine modulators and the array of metabolic

**FIGURE 5-4 General experimental design of *in vitro assays*.** Hepatocyte monocultures (a) and hepatocyte-Kupffer cell co-cultures (b) are exposed to cytokines of interest for 24 to 96 h. The cultures are then incubated with CYP probe substrates, followed by measurement of metabolite formation and mRNA levels to assess enzyme activities and gene expression.

enzymes and transporters is limited. Current practices predominantly involve the use of primary hepatocyte cultures because they are the most prevalent model employed owing to their relatively easy access and commercial availability from various preclinical species as well as from humans. In addition, plateable cryopreserved hepatocytes are commercially available, which have the advantage of reduced interassay variability. This allows an easier comparison of the effect of different test molecules than in hepatocytes freshly isolated from different donors. A general experimental design for assessing the effects of cytokines on CYP enzymes in a hepatocyte monoculture *in vitro* system is illustrated in Figure 5-4a. Hepatocyte monocultures are cultivated and then incubated with cytokines of interest for the desired period (~24–96 h). The monocultures are then exposed to CYP probe substrates, followed by measurement of metabolite formation and mRNA levels to assess enzyme activities and gene expression.

A limitation of the use of hepatocyte monocultures in studying the effect of cytokines is that typically one cytokine is studied at a time, whereas *in vivo* the liver is exposed to a wide range of immunomodulatory molecules. The question therefore is warranted whether data generated in hepatocytes are representative of *in vivo* conditions or, more important, of disease states in which the concentration of individual cytokines can be grossly altered. As a strategy to overcome this limitation, co-cultures of hepatocytes with either purified Kupffer cells[13] or nonparenchymal cell (NPC) mixtures containing immature hepatocytes, Kupffer cells, biliary cells, stellate cells, and hepatic stem cells are currently being explored.[22] These co-culture systems may offer an advantage over primary hepatocytes by providing a physiological environment that is more closely representative of an *in vivo* scenario.

A general experimental design for assessing the effects of cytokines on CYP enzymes in a hepatocyte–Kupffer cell co-culture *in vitro* system is illustrated in Figure 5-4b. Hepatocytes are co-cultured with Kupffer cells (or NPC) and then incubated with cytokines of interest for the desired period (~24–96 h).

The co-cultures are then exposed to CYP probe substrates followed by measurement of metabolite formation and mRNA levels to assess enzyme activities and gene expression.

The limited availability of *in vitro* tools for studying the impact of cytokines on liver enzymes and transporters highlights a need for more sophisticated assay systems and advocates for exploring new technologies.

## 5.4 EFFECTS OF CYTOKINES ON METABOLIZING ENZYMES AND TRANSPORTERS

### 5.4.1 IL-1 Investigations

***5.4.1.1 Effects of IL-1 on Cytochrome P450 Enzymes*** As summarized in Table 5-1, the interaction of IL-1β on CYP enzymes has been widely observed. Barker and coworkers showed in isolated rat hepatocytes that IL-1β (1–4 U/mL, 24 h) substantially reduced 2,3,7,8-tetrachlorodibenzo-*p*-dioxin-induced CYP1A1 and CYP1A2 mRNA expression by approximately 65% and 95%, respectively.[9] The inhibitory effects were dose dependent, with $IC_{50}$ at 2 and 0.5 U/mL for CYP1A1 and CYP1A2, respectively.

Similar observations of CYP enzyme suppression were made in human primary hepatocytes by numerous investigators. Abdel-Razzak and coworkers reported a reduction in activity of CYP1A2 (12–89%) by IL-1β (100 U/mL, 72 h).[10] The interaction was believed to be at the transcriptional level owing to a corresponding decrease in CYP1A2 mRNA (60–93%). IL-1β (100 U/mL, 24 h) also showed suppression of both basal levels and phenobarbital- and bilirubin-mediated induction of CYP2B6 mRNA.[11] Aitken and Morgan were unable to detect similar suppression of CYP2B6 mRNA in their experimental studies with IL-1β (5 ng/mL, 24 and 40 h) but did observe reduced CYP2B6 protein levels and a corresponding increased NO production.[12] Collectively, these results suggest that the IL-1β interaction with CYP2B6 may be mediated by various mechanisms, including alteration of gene transcription, inhibition of protein translation, and/or increased enzyme degradation associated with elevated NO production.

In terms of the CYP2C family, CYP2C8 and CYP2C9 mRNA expression was shown to be downregulated by IL-1β, and a significant reduction in CYP2C9 protein levels was also observed.[11,12] Similar to CYP2B6, a corresponding increase in NO production was detected in parallel with a reduction in CYP2C9 protein after IL-1β exposure.[12] This was not seen for CYP2C8 mRNA inhibition, however. These results suggest that IL-1β may interact with CYP2C8 at the level of gene transcription, whereas it may regulate CYP2C9 through both gene transcription and protein expression/degradation. In contrast to CYP2C8 and CYP2C9, CYP2C18 and CYP2C19 mRNA levels were unaffected by IL-1β.[12]

Analogous to the other CYP enzyme families, IL-1β also negatively affected CYP3A4 mRNA expression, protein levels, and enzyme activity. Abdel-Razzak's group reported that IL-1β (100 U/mL, 72 h) produced significant reduction in gene expression (60–93%) and CYP3A4 activity (30–90%).[10] Similarly, Assenat and

coworkers reported IL-1β suppression of both basal and phenobarbital- and bilirubin-mediated induction of CYP3A4 mRNA expression (100 U/mL, 24 h).[11] Aitken and Morgan also demonstrated significant downregulation of CYP3A4 mRNA expression (>95%) accompanied with a corresponding decrease in CYP3A4 protein after IL-1β exposure (5 ng/mL, 24 h and 40 h).[12] Thus IL-1β regulation of CYP3A4 appears to be most likely at the transcriptional level.

Assenat and coworkers hypothesized that the mechanism by which IL-1β interacts with CYP3A4 and other CYP enzymes at the level of gene transcription may potentially be through the downregulation of CAR expression.[11] This was supported by demonstrating that IL-1β activated NF-κB, which led to the downregulation of glucocorticoid receptor (GR) transactivation of the CAR promoter, resulting in suppressed CAR mRNA expression and decreased CAR-mediated gene transcription. Another potential regulatory mechanism associated with IL-1β may involve the downregulation of RXRα and PXR mRNA, leading to altered gene expression of CYP enzyme.[38]

Post-transcriptionally, NO-induced enzyme degradation may also be involved in the regulation of the CYP3A family.[37] Although mRNA levels were unaffected by IL-1β in primary rat hepatocytes, Lee and coworkers detected a 40% downregulation of CYP3A1 protein.[37] This inhibition in protein expression was reversed by NO synthase inhibitors.

***5.4.1.2 Effects of IL-1 on Phase II Metabolizing Enzymes*** Although not as extensively studied, various phase II metabolic enzymes have also been shown to also be affected by proinflammatory cytokines (Table 5-2). Abdel-Razzak and coworkers reported that in human primary hepatocytes IL-1β was a potent suppressor of various enzymes including epoxide hydrolase.[10] Assenat's group showed that IL-1β (100 U/mL, 24 h) suppressed both basal expressions and phenobarbital- and bilirubin-induced UGT1A1, GSTA1, and GSTA2 mRNA.[11] The authors suggest that similar to CYP3A4, IL-1β regulation of phase II metabolic enzymes may also involve the activation of NF-κB, leading to inhibition of GR-mediated CAR mRNA expression.

In rat primary hepatocytes, IL-1β (20–300 U/mL, 8–48 h) produces a marked decrease in basal mRNA levels of rGSTA2 and rGSTM1, with a corresponding decrease in rGSTM1 protein expression (~44%) and activity (47–78%).[39] In addition, IL-1β also suppressed 3-methylcholanthrene-, phenobarbital-, and/or oltipraz-induced expression of rGSTA2 and rGSTM1 mRNAs and proteins. Associated with these findings a shorter mRNA half-life was observed, suggesting the effects of IL-1β on GST were the result of mRNA destabilization rather than reduced gene transcription. In contrast to rGSTA2 and rGSTM1, IL-1β exposure led to increased rGSTP1 mRNA levels and had no effect on the chemically induced expression of both rGSTP1 mRNA and protein.

***5.4.1.3 Effects of IL-1 on Drug Transporters*** In addition to metabolizing enzymes, drug transporters are also affected by proinflammatory cytokines (Table 5-3). Sukhai and coworkers observed that IL-1β (0–50 ng/mL, 72 h) had no

effect on Mdr1a or Mdr1b mRNA in primary rat hepatocytes, but P-glycoprotein (P-gp) protein expression was significantly reduced (32–75%), which also corresponded with a reduction in efflux activity.[42] Because no effects were observed on Mdr1 gene expression, the effect of IL-1β on P-gp is potentially mediated through either protein synthesis and/or protein stability in rat hepatocytes. Diao's group detected a significant decrease in levels of MRP2 protein in sandwich-cultured (SC) rat hepatocytes but not mRNA in the presence of IL-1β (1 ng/mL, 24 and 48 h).[44] They also saw downregulation of both Bsep gene expression (Abcb11 mRNA) and protein levels in the presence of IL-1β.

General IL-1β suppression of transporters was also observed in human primary hepatocytes and HepaRG cells by Le Vee and coworkers whereby mRNA expression, protein levels, and transporter activities were reduced for both organic anion transporting polypeptide (OATP) 1B1 and sodium-taurocholate co-transporting polypeptide (NTCP).[43] Analogous observations were also made by Assenat's group: IL-1β (100 U/mL, 24 h) suppressed both basal and phenobarbital- and bilirubin-induced expression of OATP1B1 mRNA expression.[11] Besides OATP1B1 and NTCP, downregulation of gene expression was also detected for other uptake transporters such as OATP1B3 and OATP2B1 and efflux pumps such as multidrug resistance protein (MRP) 2, MRP3, and MRP4 and breast cancer resistance protein (BCRP).[43] The reduction in MRP2 gene expression was similarly confirmed by Diao and coworkers as was reduced protein levels after IL-1β exposure in SC human hepatocytes.[44] It is interesting that IL-1β also diminished BSEP gene expression, but protein levels were significantly induced.[44] This finding was contradictory to the reduction in BSEP protein expression observed in HepaRG cells by Le Vee and colleagues.[43] The discrepancy highlights one of the challenges of the *in vitro* system; interlab variability can limit data reproducibility and limit result interpretation.

### 5.4.2 IL-2 Investigations

***5.4.2.1 Effects of IL-2 on Cytochrome P450 Enzymes*** Tinel and coworkers reported exposure to IL-2 in rat hepatocytes caused a decrease in mRNA levels of CYP3A2 and CYP2C11 and a corresponding reduction in protein expression of CYP1A1 (35%), CYP2B1/2 (35%), CYP2C11 (36%), CYP2D1 (26%), and CYP3A (56%).[14] The interaction of IL-2 on the various CYP enzymes may primarily be at the transcriptional level.

In the clinic, IL-2 has been observed to suppress both activity and protein levels of CYP3A.[51,52] *In vitro*, using cultured primary human hepatocytes, the inhibitory effect was transient with suppression observed at 48 h but returned to baseline at 72 h.[13] However, when Kupffer cells were co-cultured with hepatocytes at physiologically relevant ratios of 10:1 and 10:4 (hepatocytes to Kupffer cells), representing "normal" and "inflamed" states, respectively, IL-2 showed prolonged suppression of CYP3A activity (50–70%) out to 72 h in the co-cultures. Results suggest that the co-culture system may be more physiological representative and thus can offer an advantage for studying the effects of

cytokines, whereas hepatocytes alone are insufficient. The authors proposed that IL-2 effects on CYP3A may be through multiple mechanisms, including: direct binding to the hepatocytes IL-2R to produce a transient suppression of CYP3A; indirectly stimulating Kupffer cells to secret other proinflammatory cytokines, such as IL-1, IL-6, and TNF-α;[52] and indirectly stimulating Kupffer cells to release other proinflammatory mediators, such as prostaglandins, prostacyclins, and eicosanoids, which have been shown to regulate CYP activity. Further work is needed to investigate these hypotheses and the applicability of the hepatocyte-Kupffer cell co-culture system in general.

***5.4.2.2 Effects of IL-2 on Drug Transporters*** In Caco-2 cells, IL-2 significantly reduced P-gp transport of rhodamine-123 (21%) (100–5000 IU/mL, 24–72 h) and strongly suppressed MDR1 mRNA levels (1000 IU/mL, 72 h).[45] Currently, the mechanism by which IL-2 interacts with P-gp is unknown.

### 5.4.3 IL-4 Investigations

Limited ADME-related work has been reported for cytokine IL-4. Abdel-Razzak and colleagues noted variable effects of IL-4 (150 U/mL, 72 h) on CYP enzymes in human primary hepatocytes, in contrast to the usual suppressive effects observed with other proinflammatory cytokines. In their investigation, IL-4 appeared to have no effect on CYP1A2 and CYP2C gene expression, whereas CYP2E1 mRNA levels were significantly induced by five-fold.[10] Effects of IL-4 on CYP3A mRNA expression and activity were also not observed.

### 5.4.4 IL-6 Investigations

***5.4.4.1 Effects of IL-6 on Cytochrome P450 Enzymes*** As one of the major proinflammatory cytokines, IL-6 effects on CYP enzymes have been widely reported. Initially, in contrast to results from IL-1β exposure, early work by Barker and coworkers did not show an effect of IL-6 on 2,3,7,8-tetrachlorodibenzo-*p*-dioxin-induced CYP1A mRNA expression in rat hepatocytes.[9] However, later investigations in human primary hepatocytes produced consistent inhibitory effects by IL-6 on various CYP enzymes. The discrepancy highlights inherent interlab variability owing to a lack of standardization of experimental design and/or species evaluated, which is a limiting factor of the *in vitro* system. IL-6 suppression of CYP1A2 activity (18–90%) has been reported by Abdel-Razzak's group (50 U/mL, 72 h),[10] Guillen's group (100 U/ml, 48 h),[15] and Dickmann's group (0.005–50 ng/mL, 24–96 h).[18] In parallel with decreased enzyme activity, similar inhibition of CYP1A2 mRNA levels (25–%)[18] and protein expression were also detected.[15] It is interesting that Dickmann and coworkers demonstrated that the incorporation of an IL-6 neutralizing mAb can completely block IL-6 suppression of CYP1A2 activity.[18]

In regard to the mechanism of interaction, Guillen and coworkers noted that measured NO levels were unchanged in cytokine-treated and untreated hepatocytes, suggesting that IL-6 interaction with CYP1A2 may not be attributed to enzyme degradation associated with NO biosynthesis.[15] Abdel-Razzak and coworkers suggested that the presence of an IL-6-response element in the 5′ flanking regions of the CYP1A1/1A2 genes may play a role in the transcriptional regulation of CYP genes by IL-6.[10]

In addition to CYP1A2, IL-6 also had significant impact on CYP2B6 enzyme. Guillen and coworkers reported a 48% reduction in CYP2B6 activity by IL-6 (100 U/mL, 48 h),[15] which was consistent with results from Aitken and Morgan, who found IL-6 exposure (10 ng/mL, 24 h and 40 h) in human primary hepatocytes led to substantial suppression of both CYP2B6 mRNA (80%) and protein levels (25–50%).[12] Pascussi and colleagues also confirmed IL-6- mediated (100 U/mL, 24 h) inhibition of both CYP2B6 basal mRNA levels (60%) as well as phenobarbital- and rifampicin-induced mRNA levels (80–90%).[16] Guillen's group proposed that, similar to the interaction with CYP1A2, the effect of IL-6 on CYP2B6 may not be through protein degradation but most likely mediated by transcriptional regulation.[15] This was supported by Pascussi's group, who reported rapid and marked decrease in PXR (~80%) and CAR (~60%) mRNA expression in the presence of IL-6 (100 U/mL, 6 h).[16] These results suggest that the IL-6-mediated suppression of both PXR and CAR could potentially be the regulatory mechanism associated with the effects of IL-6 on rifampicin- and phenobarbital-induced CYP2B6 expression.

Consistent with the other CYP enzymes, IL-6 inhibition of the CYP2C family has also been observed. The mRNA levels of CYP2C8, CYP2C9, and CYP2C19 in general were decreased (25–80%) in the presence of IL-6.[10,12,16,18] The suppression of rifampicin- and phenobarbital-induced CYP2C8 and CYP2C9 mRNA expression (80–90%) was also observed after IL-6 exposure.[16] In addition, similar changes in CYP2C9 protein levels (25–50% suppression) were reported by Aitken and Morgan.[12] In contrast to the general inhibitory effects on the CYP2C family, IL-6 exposure did not affect CYP2C18, perhaps owing to the low basal levels of expression of this enzyme in the liver.[12]

The effects of IL-6 on the CYP3A family have also been extensively studied. Suppression of CYP3A4 activity (20–80%), mRNA expression (25–90%), and protein levels (25–50%) have been reported by various labs.[10,12,13,15,18] Dickmann and coworkers also observed that, similar to CYP1A2, the incubation with an IL-6 neutralizing mAb can partially prevent IL-6 suppression of CYP3A4 activity.[18] In addition to basal CYP3A4 levels, Pascussi's group[16] and Dickmann's group[18] also reported that IL-6 exposure can lead to decreased rifampicin- and phenobarbital-induced CYP3A4 gene expression. However, this was observed only at supraphysiological concentrations. Guillen and coworkers observed no changes in NO levels with IL-6 treatment that could cause enzyme degradation.[15] Pascussi and coworkers proposed that, similar to CYP2B6, IL-6-mediated suppression of both PXR and CAR genes could potentially be the regulatory mechanism by which IL-6 mediates the inhibition of rifampicin- and phenobarbital-induced CYP3A4 expression.[16]

***5.4.4.2 Effects of IL-6 on Phase II Metabolizing Enzymes*** For phase II metabolic enzymes, IL-6 had inhibitory effects on epoxide hydrolase mRNA expression (>40%)[10] but no interaction with glutathione *s*-transferase (GST) enzymes[40] when studied in human primary hepatocytes.

***5.4.4.3 Effects of IL-6 on Drug Transporters*** Unlike IL-1β, IL-6 (0–50 ng/mL, 24 h) treatment of rat hepatocytes significantly downregulated Mdr1b mRNA expression, suppressed P-gp protein levels (20–38%), and reduced P-gp-mediated rhodamine-123 transport.[42] It is believed that transcriptional modulation of the Mdr1 gene may be responsible for IL-6 effects on P-gp protein and activity. Mechanisms of interaction were not investigated, but the authors proposed that owing to similarities shared between CYP and Mdr1 gene families in regard to substrates, inducers, and inhibitors there could be parallelism in regulatory mechanisms of IL-6 on Mdr genes.[53]

In addition to P-gp, Le Vee and coworkers observed that IL-6 (0.1–10 ng/mL, 8–48 h) treatment of primary human hepatocytes suppressed mRNA levels of major influx and efflux transporters, including NTCP, OATP1B1, OATP1B3, OATP2B1, OCT1, OAT2, MRP2, MRP4, and BCRP.[46] The effects on these transporters were mostly concentration dependent (NTCP, OATP1B1, OATP1B3, OATP2B1, OCT1, and BCRP) and time dependent (MDR1). On the other hand, both BSEP and MRP3 gene expression were unaffected by IL-6. In regard to protein levels, IL-6 (10 ng/mL, 48 h) did not alter P-gp but did reduce NTCP, OATP1B1, BCRP, and MRP2, and induced MRP3. Consistent with results of mRNA and protein expression, NCTP, OATPs, and OCT1 activities were also significantly reduced in human primary hepatocytes. Although the mechanisms of the effects were unexplored, modulation of gene transcription leading to suppressed protein and activity levels may explain how IL-6 interacts with NCTP, OATP, and OCT1.

Similar to Le Vee and coworkers, Diao's group observed significant IL-6 (100 ng/mL, 24–48 h) downregulation of both mRNA and protein levels of MRP2/Mrp2 in SC human and rat hepatocytes.[44] On the other hand, variable results were reported with BSEP in SC human hepatocytes: IL-6 suppressed mRNA transcription while inducing protein levels. In SC rat hepatocytes, however, *Bsep* gene expression was induced but no effects were seen on protein levels. Collectively, results demonstrate a differential effect of BSEP/Bsep expression between SC human and rat hepatocytes most likely attributed to species-dependent signaling pathways.

The mechanism of IL-6 regulation was uninvestigated, but it is believed to involve both transcriptional mechanisms associated with the phosphorylation of extracellular-reactive kinase (ERK), Jun kinase (JNK), and p38 mitogen-activated protein kinase (MAPK) as well as post-transcriptional mechanisms.[26,43,54]

### 5.4.5 Oncostatin

***5.4.5.1 Effects of Oncostatin on Cytochrome P450 Enzymes*** Oncostatin M (OSM) is a multifunctional cytokine that is related to IL-6. Both have overlapping biological effects in many cellular systems owing to similarity in structure,

function,[55,56] and signal transduction pathway activation.[57–59] OSM acts on a wide variety of cells: It regulates growth of certain tumor and nontumor-derived cell lines,[60,61] induces cell differentiation,[55,62] and upregulates low-density lipoprotein in liver cells[63] and acute phase protein in hepatocytes (i.e., α1-antichymotrypsin, haptoglobin, and α1-acid glycoprotein).[64]

Guillen and coworkers demonstrated that in human primary hepatocytes exposure to OSM (25–50 U/mL) produced maximal reductions in CYP1A2 (~55%) and CYP3A4 (~30%) activity after 48 h of treatment.[15] Comparable decreases were also observed for CYP2A6 (30%) and CYP2B6 (62%). The inhibitory effects of OSM on CYP enzymes were also detected after induction of both CYP1A2 and CYP3A4 by 3-methylcholanthrene (MC) and dexamethasone (DEX), respectively. MC-induced CYP1A2 showed a sixfold increase in activity compared to an uninduced control. In the presence of OSM (25 U/mL), only 43% of the induced CYP1A2 activity was detected. Similarly, DEX-induced CYP3A4 activity was increased twofold, and in the presence of OSM 47% of induced CYP3A4 activity was observed.

Reported OSM suppression of CYP activities was consistent with observed protein levels. The presence of OSM in increasing concentration (up to 50 U/mL) resulted in decreased protein synthesis of both CYP1A2 and CYP3A4. After MC- and DEX-induction of CYP1A2 and CYP3A4, respectively, protein levels were increased by ~60% (CYP1A2) and ~100% (CYP3A4) of uninduced control. Introducing OSM after induction inhibited the synthesis of both CYP1A2 and CYP3A4 enzymes to levels that were similar to uninduced cells. OSM presence did not alter NO synthesis; therefore, its effect on CYP protein levels was not attributed to NO.

Parallel to activities and protein synthesis, significant reduction of CYP1A2 and CYP3A4 mRNA expression occurs in the presence of OSM (50 U/mL).[15] This suggests that OSM regulation of CYP enzymes may occur at the transcriptional level, perhaps by similar mechanisms as the related cytokine IL-6, whereby PXR and CAR mRNA levels were altered.[16]

***5.4.5.2 Effects of Oncostatin on Drug Transporters*** In addition to CYP enzymes, Le Vee and coworkers also evaluated the effects of OSM on sinusoidal and canalicular drug transporters in human primary hepatocytes.[47] Exposure to OSM (0.01–20 ng/mL, 8–48 h) produced no effects on P-gp, MRP3, MRP4, and BSEP mRNA expression. In contrast, OSM exposure led to the downregulation of mRNA levels of major sinusoidal solute carrier (SLC) influx transporters (NTCP, OATP1B1, OATP1B3, OATP2B1, OCT1, and OAT2) as well as ATP-binding cassette (ABC) efflux transporters (MRP2 and BCRP). The OSM $EC_{50}$ of mRNA expression ranged between 0.12 and 1.16 ng/mL in human primary hepatocytes. Correspondingly, the protein expression of NTCP, OATP1B1, OATP2B1, and BCRP along with transport activities of NTCP and OATP were also inhibited after OSM exposure.

Rank correlation analysis of suppressive effects of OSM toward drug transporters showed that OSM effects were highly correlated with those of IL-6 and, in a more moderate manner, with those of IL-1β. By contrast, they were not correlated with those of TNF-α and IFN-γ. Type II OSM receptor has been implicated as a

mediator of OSM transcriptional regulation of these various transporters. Knocked-down expression of the type II OSM receptor gp130 and OSMRβ subunits with siRNA transfection has counteracted the downregulation of NTCP, OATP1B1, and OATP2B1 mRNA expression. Le Vee and coworkers hypothesized that the signaling pathway that is activated by this receptor, especially by its signal-transducing component gp130 subunit, may play a major role in OSM-related changes in transporter expression.[47] This is further supported by the fact that altered transporter expression owing to OSM treatment was highly correlated with inhibitory effects triggered by IL-6 and that the IL-6 receptor also uses the gp130 subunit for signal transduction.[65] OSM and IL-6 are known to activate several distinct signaling pathways through the gp130 subunit, including the Janus kinase/signal transducer and activator of transcription cascade, the MAPK pathway, and the phosphatidylinositol 3-kinase pathway.[66] In agreement with these data, the MAPK ERK was found to be activated by OSM.[47]

### 5.4.6 TNF-α Investigations

***5.4.6.1 Effects of TNF-α on Cytochrome P450 Enzymes*** Abdel-Razzak and coworkers observed substantial inhibition of CYP1A2 (30–85%) and 3A activities (24–90%) by TNF-α (50 U/mL, 72 h) in human primary hepatocytes.[10] Analogous reduction in mRNA expression of these enzymes (30–80%) was also detected, indicating a probable transcriptional component to TNF-α effects on these enzymes.[10,12]

Similar to CYP1A2 and CYP3A, gene expression of CYP2C and CYP2E1 was also negatively affected by the presence of TNF-α, with 30–80% inhibition observed.[10] On the other hand, Aitken and Morgan observed only minimal interactions of TNF-α (10 ng/mL, 24 h and 40 h) with mRNA expression of CYP2B6, CYP2C9, CYP2C18, and CYP2C19 in human primary hepatocytes.[12] Despite minor effects on gene expression, CYP2B6 and CYP2C9 protein levels were inhibited, suggesting that TNF-α may interact with these enzymes through modification of protein translation and/or enzyme degradation. The differential effects of TNF-α on various CYP enzymes highlights potentially different regulatory mechanisms involved. TNF-α may regulate CYP3A4 at the transcriptional level, possibly via NF-κB interference with the PXR-RXR complex as suggested by Gu and coworkers (Figure 5-3b) and, in contrast, affect the translation and/or stability of either CYP2B6 or CYP2C9 enzymes.[19]

***5.4.6.2 Effects of TNF-α on Phase II Metabolizing Enzymes*** Limited studies have been dedicated to evaluating the effects of TNF-α on the phase II metabolic enzymes. Abdel-Razzak's group has observed, however, a decrease of epoxide hydrolase mRNA levels in human primary hepatocytes.[10]

***5.4.6.3 Effects of TNF-α on Drug Transporters*** Several studies have increased the understanding of the interaction between TNF-α and the various drug transporters. In rat primary hepatocytes, Hirsch-Ernst and coworkers observed that

TNF-α (4000 U/ml, 72 h) exposure led to a twofold induction of Mdr1b mRNA and P-gp protein and a corresponding decrease in intracellular accumulation of the P-gp substrate rhodamine-123.[48] It was postulated that the induction of Mdr1b mRNA may have been due to elevated oxygen species associated with the presence of TNF-α. Reactive oxygen species have been implicated as a mediator of various TNF-α effects, including activation of NF-κB,[67] stimulation of gene transcription,[68] and alteration of protein phosphorylation.[67] After treating rat primary hepatocytes with antioxidants, Hirsch-Ernst and coworkers detected marked suppression of TNF-α-induced Mdr1b Pgp mRNA and protein levels.[48]

Inhibition of Mdr1 mRNA (56%) was measured in human Caco-2 cells after treatment with TNF-α (1–10 ng/mL, 24–96 h) by Belliard's group.[49] In contrast to the results from rat hepatocytes, however, the suppressed gene expression did not translate to a decreased P-gp protein level but did decrease (20%) unidirectional transport of rhodamine-123. The discrepancy in TNF-α induction/suppression of Mdr1 may be attributed to differences in the experimental models (rat hepatocytes vs. human carcinoma cell lines) and/or differences in regulatory mechanisms in rat and human.

Besides P-gp, TNF-α interaction with MRP2 and BSEP were assessed by Diao and colleagues in both SC human and rat hepatocyte models.[44] After TNF-α treatment (100 ng/mL, 24 and 48 h), significant suppression of both mRNA and protein levels were measured for MRP2/Mrp2 in SC human and rat hepatocytes. On the other hand, variable results were detected with BSEP in SC human hepatocytes as TNF-α-suppressed mRNA transcription but showed no effects on protein. In SC rat hepatocytes, however, both Bsep mRNA and protein levels were reduced by TNF-α. Similar to IL-6, results demonstrate a differential effect of BSEP/Bsep expression between SC human and rat hepatocytes that may be attributed to species-dependent signal transduction pathways. Similar to IL-1β and IL-6, regulation by TNF-α may involve transcriptional mechanism associated with the activation of ERK, JNK, and p38 MAPK phosphorylation.[26]

Le Vee's group observed that in human primary hepatocytes incubation with TNF-α (0.01–100 ng/mL, 8–48 h) led to significant reduction of NTCP, OATP2B1, OATP1B1, OATP1B3, OCT1, OAT2, and BSEP mRNA, whereas mRNA levels of MDR1, MRP2, MRP3, MRP4, and BCRP were unchanged.[46] The effects were mostly concentration dependent (0.01–100 ng/mL), with marked inhibition of gene expression at ~1 ng/mL TNF-α. In regard to protein expression, TNF-α incubation did not alter MRP2 and P-gp protein levels (corresponding to unaltered gene expression), but NTCP and OATP1B1 levels were reduced and BCRP and MRP3 were induced. Consistent with mRNA and protein expression results, NCTP, OATP, and OCT1 activities were also significantly decreased in human primary hepatocytes. For these transporters, although the mechanism of interaction was unexplored, experimental outcomes suggest that regulation by TNF-α may be at the transcriptional level.

### 5.4.7 IFN Investigations

***5.4.7.1 Effects of IFN-γ on Cytochrome P450 Enzymes*** The interaction of IFN with CYP1A2 has been extensively observed in human primary hepatocytes.

In general, downregulation of CYP1A2 basal activity (29–53%) and 3-methylcholanthrene-induced activity (32%) was observed in the presence of IFN-γ (50–300 U/mL, 24–72 h).[10,15,20] The decrease in activity was consistent with lowered mRNA (up to ~40%)[10]and diminished basal and 3-methylcholanthrene-induced CYP1A2 protein expression (72%).[15,20] These results suggest that the interaction of IFN-γ with CYP1A2 is most likely mediated through gene transcription. However, post-transcriptional regulation may also play a contributing factor because IFN-γ has previously been shown to suppress CYP1A2 activity in parallel with markedly elevated NO production.[20] Besides IFN-γ, IFN-α2b has also been shown to produce analogous inhibition of CYP1A2. Similarly, IFN-α2b can also interact with the interferon receptor to influence the upregulation or downregulation of various genes in the liver.[69]

Similar to CYP1A2, suppression of CYP2A6 and CYP2B6 activities were also observed in the presence of IFN-γ (300 U/mL, 24 h).[15,20] This decrease was in parallel to elevated NO production, which was partially reversed by the presence of an inhibitor of NO biosynthesis ($N^G$-monomethyl-L-arginine). Associated with the activity suppression, Aitken and Morgan also saw significant inhibition of CYP2B6 mRNA (80%) and protein levels (~65%) after exposure to IFN (10 ng/mL, 24 h).[12] It appears that IFN may regulate CYP2A6 and CYP2B6 by both gene transcription (as evident by changes in mRNA levels) and enzyme stability (influenced by increased NO biosynthesis).

Like other CYP enzymes, IFN downregulated CYP3A activity (21–55%) but had no effect on gene expression after incubation with IFN-γ (50 U/mL, 72 h).[10] On the other hand, IFN-γ at 300 U/mL for 24–48 h elicited suppression of both basal and DEX-induced CYP3A4 activity (20–34%), along with reduced mRNA ($\geq$ 80%) and protein levels (~ 50%).[12,15,20] Discrepancy in gene expression results may be attributed to differences in donors and/or experimental conditions. The noted changes in mRNA expression suggest a transcriptional component in IFN regulation of CYP3A4. In addition, Donato and coworkers detected elevated NO biosynthesis in parallel with CYP3A4 inhibition and a partial reversal of the inhibition after incorporation of $N^G$-monomethyl-L-arginine to culture media, similar to CYP1A2.[20] These findings suggest that enzyme stability may have a minor role in IFN regulation of the CYP3A family.

In contrast to the other CYP enzymes, IFN in general does not appear to have much interaction with the CYP2C family. With the exception of CYP2C8, for which significant mRNA reduction was detected, no effects were observed on the gene expression of CYP2C9, CYP2C18, and CYP2C19 after IFN-γ (10 ng/mL, 24 and 40 h) incubation in primary human hepatocytes.[10,12]

Chen's group assessed the impact of IFN-α2b on the expression of various drug-metabolizing enzymes in freshly prepared human primary hepatocytes co-cultured with nonparenchymal cells (which included a mixture of immature hepatocytes, Kupffer cells, biliary cells, stellate cells, and hepatic stem cells).[22] At therapeutically relevant concentrations (1000–3000 U/mL), IFN-α2b was shown to downregulate mRNA expression of several metabolizing enzymes, including CYP1A2,

CYP2B6, and CYP2E1. The observed downregulation of mRNA was as high as 50%, with a corresponding decrease in protein expression. Conversely, significant upregulation of CYP3A4 mRNA and protein expression was detected. The observed induction of CYP3A4 in this experimental system was unexpected and in contrast to CYP3A4 suppression detected by Guillen's group[15] with IFN and Aitken and Morgan[12] with IFN-γ. Possible mechanisms mediating this effect are currently unknown and require further elucidation. In contrast to CYP3A4, IFN-α2b suppression of CYP1A2, CYP2B6, and CYP2E1 mRNA and protein expression could potentially be attributed to regulation at the transcriptional level owing to substantial inhibition of CYP gene expression.

***5.4.7.2 Effects of IFN-γ on Phase II Metabolizing Enzymes*** In human primary hepatocytes co-cultured with nonparenchymal cells, IFN-α2b (at therapeutically relevant concentrations of 1000–3000 IU/mL) was shown to have an impact on the expression of various phase II metabolizing enzymes, including the downregulation of UDP-glucuronosyltransferase (UGT2B7) and sulfotransferase (SULT1A1) mRNA expression.[22] Similar to gene expression, UGT2B7 protein levels were also inhibited. Although the regulatory mechanism remains to be elucidated, transcriptional modulation leading to altered protein expression is most likely a method by which IFN-α2b interacts with the various phase II metabolic enzymes. In contrast to UGT2B7 and SULT1A1, IFN-α2b showed no significant effect on the mRNA expression of SULT2A1, carboxylesterase 2 (CES2)[22] or epoxide hydrolase.[10]

***5.4.7.3 Effects of IFN-γ on Drug Transporters*** Belliard and coworkers observed induction of both MDR1 mRNA (2.5-fold) and P-gp protein levels when Caco-2 cells were incubated with IFN-γ (10 ng/mL, 24–72 h).[49] The increased protein expression, however, did not alter P-gp efflux activity. Confocal laser scanning microscopy showed altered distribution of P-gp with more co-localization with lateral F-actin, which may explain the absence in correlation between the upregulation of P-gp expression by IFN-γ and the absence of a change in P-gp activity.

In human primary hepatocytes, while gene expression of both OAT2 and OCT1 remained unchanged, a general downregulation of mRNA levels of both sinusoidal influx transporters (NTCP, OATP1B1, OATP1B3, and OATP2B1) and efflux transporters (MDR1, MRP2, MRP3, BCRP, and BSEP) was detected after treatment with IFN-γ (10 ng/mL, 24 h).[50] The opposite was observed when human hepatocytes were co-cultured with nonparenchymal cells and exposed to IFN-α2b.[22] In general, there was no significant effect on the mRNA expression of OATP1B1, OATP1B3, OATP2B1, OCT1, P-gp, and BCRP at therapeutically relevant IFN-α2b concentrations (1000–3000 IU/mL). The only exception was a significant decrease in both mRNA and protein expression of OAT2. The mechanism of interaction is most likely at the level of gene transcription, leading to altered protein expression.

## 5.5 SUMMARY AND CONCLUSION

In general, with further characterization and validation, the primary hepatocyte monoculture system does add value as an *in vitro* tool for studying the effects of proinflammatory cytokines on metabolizing enzymes and drug transporters. As an isolated system, hepatocyte monocultures are useful for exploring the mechanisms of interaction between cytokines and drug-metabolizing enzymes and transporters. Furthermore, the commercial availability of hepatocytes from numerous preclinical species and from humans makes them an easily accessible experimental tool to facilitate better understanding of the effects of proinflammatory cytokines in potential toxicological species as well as potential future clinical extrapolation. In addition, the commercial availability of plateable cryopreserved hepatocytes also offers the advantage of reducing interassay variability.

On the other hand, despite some advantages current utility of the hepatocyte monoculture system has limitations (Figure 5-5), including incomplete mechanistic understanding of CYP downregulation and lack of agreement on positive controls representing various pathways. It should also be recognized that mimicking the complex effects of disease state on ADME genes *in vitro* may not be feasible. Furthermore, currently only qualitative assessment of the effects of proinflammatory cytokines on CYP enzymes and transporters can be ascertained in this experimental model. The literature reviewed here illustrates that the overall downregulation of CYP enzymes and transporters can be detected when assessed with the major proinflammatory cytokines (IL-1, IL-6, TNF-α, and IFN-γ), however, the limitation of this *in vitro* model is more apparent when extrapolation of these data to clinical

**FIGURE 5-5** Limitations of hepatocyte monocultures.

significance is needed. In addition, the lack of standardization of experimental design and study conditions across different labs also limits study reproducibility and data interpretation. Likely, the hepatocyte monoculture system can facilitate assessment only with cytokines that have receptors expressed on the hepatocytes. This limits the utility of the experimental system for cytokines that do not bind directly to receptors expressed on hepatocytes but can still render an effect on CYP enzymes and transporters indirectly through stimulation of nonparenchymal cells (i.e., Kupffer cells). These cells could release proinflammatory cytokines that can in turn act on the hepatocytes. Last, because the monoculture system is an isolated system with no interacting cytokines, supra-physiological concentrations of studied cytokines may be needed to elicit an effect. As a result of all the drawbacks from the hepatocyte monoculture experimental system, interest is gaining for a more inclusive and physiologically representative *in vitro* model for studying the effects of proinflammatory cytokines on the metabolic disposition of SM drugs. To this goal, work by Sunman and coworkers and Chen and coworkers attempted to implement nonparenchymal cells (including Kupffer cells) with hepatocytes in a co-culture system.[13,22] The paucity of literature on this co-culture system indicates that experience (or success) with this experimental model is limited across industry and academia. An additional complication associated with this model is the difficulty of obtaining relatively pure cellular fractions. Thus further characterization and validation of this *in vitro* co-culture model is necessary before its value can be determined.

It is well recognized across academia and industry that the limited amount of *in vitro* data that have been generated thus far limits the use of the hepatocyte monoculture model as a predictive tool for clinical DDIs. In general, these limitations are related to the lack of acceptable and uniformly available models that have been demonstrated to provide not only reasonable *in vitro–in vivo* correlations but also mechanistic rationale defining the limitations of such models. Hence,it is now widely recognized that there is a need to generate more *in vitro* data, especially for biologics that have been clinically shown to cause DDIs.

As discussed in this chapter, initial focus on changes in net CYP activities is a reasonable approach because these enzymes are involved in the metabolism of most small molecule therapeutics and can be well characterized by using established probe substrates. This exercise, however, should not preclude generation of gene expression data in parallel because this technique allows assessing gene expression of any gene of interest (particularly phase II enzymes and transporters). A primary challenge for *in vitro–in vivo* correlations will be to extend data generated *in vitro* to predict whether novel biologics will cause a net change in drug metabolism related to enzymes and transporters in patients. A particular challenge would be the difficulty in predicting DDIs that may be affected or may be variable when the DDI is evaluated relative to the stage of disease.

In conclusion, assessing changes of enzyme and transporter activity and gene expression in novel *in vitro* systems that could predict potential SM and biologic

DDIs is a valid and important effort, particularly because the clinical assessment of such DDIs is long, difficult, and expensive.

# USE OF ANIMAL MODELS FOR PROJECTION OF CLINICAL DRUG–DRUG INTERACTIONS FOR THERAPEUTIC PROTEINS

EUGENIA KRAYNOV and MARTIN E. DOWTY

## 6.1 INTRODUCTION

Animal models play an important role in assessing various aspects of a drug candidate during its discovery and clinical development, including anticipated efficacy, pharmacokinetics, and safety. At the same time, there are limitations with animal models in that they do not always reproduce human pathophysiology or disease drivers, pharmacokinetic pathways, or safety mechanisms relevant to humans. Hence the application of animal models must be underpinned by an understanding of the translatability of relevant mechanisms to humans. The most valuable insight into drug–drug interaction (DDI) potential is predicated on a thorough comprehension of the pharmacokinetic (PK) and pharmacodynamic (PD) properties of both interacting drugs and an understanding of their potential to be a DDI victim as well as a perpetrator.

The use of *in vitro* human systems to predict clinical DDIs of small molecules mediated through cytochrome P450 (CYP) metabolism has seen significant value.[1] However, DDI mediated through non-CYP mechanisms requires greater effort to understand *in vitro–in vivo* correlations (IVIVCs). Although the preclinical DDI assessment for therapeutic proteins can theoretically be addressed by using *in vitro* human systems alone, the relevance of the *in vitro* data in the context of a more complex *in vivo* system requires greater validation. *In vivo* animal models can potentially help bridge this gap. However, additional work is needed to address the potential for animal models to provide insight into DDI predictions of therapeutic proteins.

## 6.2 SELECTION OF THE ANIMAL MODEL

In general, a valid animal model should at least have qualitative similarity to humans in drug-metabolizing enzymes and transporters, substrate specificity, response to the inhibitor or inducer (small molecule or therapeutic protein), and disposition mechanisms of both small molecule and therapeutic proteins. These considerations depend on the breadth of questions being asked.

When it comes to evaluation of therapeutic protein–small molecule DDIs, animal models may be used to qualitatively characterize an alteration in absorption, tissue distribution, excretion, or inhibition and induction of metabolism of the small molecule (SM) drug.[2] These processes reflect changes in uptake or efflux transporters and drug-metabolizing enzymes. However, all animal species differ from humans in amino acid sequence identity and substrate specificity of drug-metabolizing enzymes and transporters. The rat is a particularly common species used in preclinical development, although rats have a greater variability in expression and extent of activity in phase I and II drug-metabolizing enzymes and typically metabolize SM drugs considerably faster than do humans.[3–5]

More similarities are found in species more closely related to humans in an evolutionary sense, in particular monkeys.[2] Rhesus and cynomolgus monkeys are used routinely for preclinical pharmacokinetics, pharmacodynamics, and safety evaluations and more recently for the study of *in vivo* drug interactions. For example, cynomolgus monkey CYP3A8 shows 93% homology to human 3A4 (a significant metabolizing enzyme for small molecules), and rhesus monkey CYP3A64 has been shown to be 93% homologous to human CYP3A4 and 83% homologous to CYP3A5.[6]

Genetically modified mouse models in which a specific gene is removed or replaced are powerful tools for various mechanistic studies.[7,8] However, there are important considerations in their successful implementation. For example, modification of a given gene does not always result in the anticipated phenotype. Therefore, interpretation of the significance of the findings from studies using genetically modified mouse models is not always as straightforward as one would expect, especially when it is desired to extrapolate the findings to humans. Nevertheless, knockout and transgenic animal models can play an important role in understanding mechanisms and may become more useful in the future.

For monoclonal antibody (mAb) based therapeutic proteins, species selection depends on mAb cross-reactivity because target-mediated clearance often plays a role in their elimination. A general limitation of rodent models is that therapeutic proteins intended for human use may not cross-react with the rodent target. A rodent-specific surrogate therapeutic protein may provide value in this regard but requires additional effort to develop and assess. In many cases, the pharmacokinetics of therapeutic proteins and its extrapolation to humans is best understood in monkeys because the therapeutic proteins are typically cross-reactive to monkey targets.

Currently no preclinical *in vivo* DDI evaluation is typically being performed for therapeutic proteins. However, given the aforementioned, in most cases the monkey is probably the most appropriate species for preclinical *in vivo* characterization of

DDIs involving therapeutic proteins if such evaluation is attempted. Monkeys generally need to be naive—that is, not previously treated with biotherapeutics (BioTx) of a similar class, to avoid formation of antidrug antibodies (ADAs) confounding the interpretation of these studies.

## 6.3 STUDY DESIGN

When a therapeutic protein is designed to be coadministered with a narrow therapeutic index (TI) drug, clinical DDI studies may need to be conducted even when there is no known mechanism of interaction. A preliminary evaluation of this interaction in the appropriate animal DDI model can aid in the design of the clinical study. Preclinical *in vivo* evaluation can be conducted for any therapeutic protein intended to be used in combination (with small molecule or another protein therapeutic drug). Combination therapy is now a standard approach in oncology and frequently used in a number of inflammatory and autoimmune diseases.

For a therapeutic protein intended to be used as a single agent and for which no known DDI mechanisms exist, it would be difficult to design an appropriate preclinical DDI study, and in most cases such evaluation is not needed.

Multiple aspects of therapeutic protein PK need to be taken into account when designing an animal DDI study with a small molecule drug. In the case of mAbs, for example, the differences in half-life—typically days for mAbs vs. only hours for small molecules—can affect the time of assessment. An interacting small molecule drug could also alter the expression of the mAb target over time or affect the disposition of the mAb. For mAbs undergoing significant target-mediated elimination characterized by nonlinear pharmacokinetic profiles, the relevance of the animal species and the study design would need to account for this interaction.[9]

From a bioanalytical perspective, the potential interference of each concomitant drug on the quantification of the other should be investigated. Quantification of small molecule drugs typically uses liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) assays, whereas analytical methods for detection of therapeutic proteins are mostly based on ligand-binding assays. The specificity and selectivity of ligand-binding assays largely rely on the reagents used in the assays and the matrices in which the samples are collected. Because there is no extraction step included in this procedure, coadministered drugs could potentially interfere with the quantification of the therapeutic protein of interest.

## 6.4 DISEASE MODELS

The only preclinical DDI evaluation being currently performed for therapeutic proteins is for cytokine-mediated DDI using human hepatocytes.[10] However, even this approach is still being optimized, and its translation to the clinical situation is not well understood.

Cytokine-mediated changes in drug-metabolizing enzymes and resulting DDIs with therapeutic proteins can potentially be evaluated in the disease models of inflammation. The adjuvant-induced inflammatory rat model shares common features with human rheumatoid arthritis with respect to development of systemic inflammation and structural changes in bone and cartilage.[11] Adjuvant treatment causes cytokine activation, resulting in a number of hepatic events, such as defenestration of sinusoids, irregular-shaped lysosomes, increased level of α1-acid glycoprotein, and lower CYP levels compared to normal rats.[12–14]

Inflammation alters expression of hepatobiliary transporters: Expression of *Oatp1a1, Oatp1a4*, and *Bsep* is downregulated in adjuvant-treated rats, while the expression of *Mrp3* is upregulated nearly by twofold.[15] Inflammatory cytokines—including tumor necrosis factor α (TNFα), interleukin 1 (IL-1), and IL-6—secreted by macrophages, and Kupffer cells have been characterized as mediators that reduce bile flow and organic anion excretion.[15]

These effects are similar to cytokine effects observed with human hepatic enzymes and transporters *in vitro* [16,17] and may at least partly reproduce the systemic pathophysiology of human rheumatoid arthritis.

In human systemic inflammatory disease, the clearance of drugs that are extensively metabolized in the liver is decreased.[18,19] Anti-inflammatory drugs should restore or normalize the amount and activity of microsomal enzymes. This was nicely demonstrated in the preadjuvant arthritis rat model after treatment with anti-TNFα mAb, infliximab.[20] The same authors earlier reported that preadjuvant arthritis is associated with elevated serum nitrite, reduced hepatic CYP content, and reduced verapamil clearance.[18] The clearance of verapamil is also reduced in patients with rheumatoid arthritis.[18] Treatment with infliximab resulted in a significant increase in total CYP, CYP1A, and CYP3A protein content in preadjuvant arthritic rats. Interestingly verapamil clearance was not significantly affected, which the authors attributed to the lack of effect on plasma protein binding.

Cytokine-mediated DDIs are typically studied *in vitro* in human hepatocytes,[16,17] and clinical DDI studies are usually conducted for high-risk therapeutic proteins. However, the IVIVC in humans is not well understood. Conceptually, this IVIVC link could be initially established using rat models of inflammation. However, the interspecies relationship may be difficult to characterize, and this may therefore reduce the predictive power of animal models. Specifically, rat and human cytokines have sufficiently low homology (e.g., mature human IL-6 shares 41% amino acid sequence identity with mouse and rat IL-6),[21] and therefore antihuman cytokine therapeutic proteins may not recognize the homologous target in a rat model. In addition, human therapeutic are likely to be immunogenic in rodents.

At present it is fair to say that while inflammatory rodent models appear to be rather straightforward, further characterization is needed.

In cases when DDI occurs via more than one pathway, animal models may be better able to reflect a net outcome of the interplay between those human-relevant pathways that otherwise would be difficult to predict from *in vitro* assays by

themselves. Even if quantitative prediction from animal models is not understood, it may still be a better qualitative predictor of potential DDI than *in vitro* studies alone. Similar to small molecule DDI, linking *in vitro* data in human and animal models to *in vivo* animals systems, may allow for more predictive DDI characterization.

## 6.5 EMERGING CHALLENGES

The structural diversity of therapeutic proteins is constantly expanding. Drug modalities representing hybrids of small molecule and proteins pose unique challenges from the DDI perspective. Included in this class are antibody-drug conjugates (ADCs) and various nanoparticles. In the case of ADCs, a small molecule is linked to a carrier antibody that provides targeting specificity through recognition of a specific target on the cell surface. As the antibody–receptor complex gets internalized, the small molecule is delivered to the target tissue where it is released. Nanoparticles can have a small molecule drug encapsulated inside while on the outside they can have specific peptides or proteins, such as mAbs that specifically deliver the small molecule to the target tissue.

These newer therapeutic protein modalities containing small molecule drugs may have a higher probability of being involved in DDI with conventional small molecule drugs. This type of DDI is more challenging to characterize *in vitro* owing to the complex and targeted nature of these drug products. One option would be to evaluate the small molecule component's DDI potential separately from the carrier or targeting moiety. However, this would not truly represent the *in vivo* situation and therefore might not adequately predict clinical behavior. Preclinical animal models may be helpful in the initial characterization of these modalities.

Biodistribution of these compounds should probably be evaluated as part of their DDI evaluation. Factors that influence tissue distribution of therapeutic proteins include size, charge, target and off-target binding properties, and route of administration.[22] For proteins that are above the glomerular filtration cutoff (such as immunoglobulins), the major elimination organs are liver and other highly perfused organs. These proteins cannot easily pass through biological membranes and distribute primarily into the vascular space and extracellular fluids.

## 6.6 CONCLUSIONS

It is important to appreciate that findings from animal DDI models should initially be characterized for qualitative information only. An appropriately selected and used animal model can be a valuable tool for DDI assessments during the drug discovery and development processes. Although clinical DDI assessment remains a necessary part of the development of therapeutic proteins, additional insight and characterization of preclinical tools, including animal models, may provide greater value in the future.

# THE COCKTAIL APPROACH AND ITS UTILITY IN DRUG–DRUG INTERACTION ASSESSMENTS FOR THERAPEUTIC PROTEINS

ALEXANDER JETTER and UWE FUHR

## 7.1 ASSESSMENT OF ENZYME ACTIVITIES USING THE COCKTAIL APPROACH

The cocktail approach is used to assess the effect of drugs on the activities of the main cytochrome P450 (CYP) enyzmes *in vivo*. As for all other drugs, any effect of therapeutic proteins on the metabolism of other (victim) drugs needs to be tested and quantified. The main mechanisms of interaction for small molecules on CYPs are enzyme inhibition by direct interaction with the enzyme, increased synthesis of enzymes via aryl hydrocarbon (Ah)- or retinoid X receptor (RXR) related processes, or decreased turnover of the enzyme (in the case of the cytochrome P450 enzyme CYP2E1). These mechanisms of interaction are related to the structural similarity of victim substrates and other small molecule drugs. Appropriate *in vitro* tests have been established for enzyme inhibition and, with limitations in quantification of the effect, also for the described mechanisms of enzyme induction. In contrast, therapeutic proteins would rarely have a direct action on the enzyme or would trigger classical enzyme induction, which developed as specific defense mechanisms to protect an organism against exposure to toxic nutritional components. Thus *in vitro* or animal studies with therapeutic proteins have limited power to predict clinical interactions because the molecular mechanisms are only partially understood and/or often cannot be mimicked in nonclinical test systems.[1] Because not all potential combinations of a therapeutic protein with other drugs can be tested in a clinical study, the effect of such drugs on drug metabolizing enzymes, mainly

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,
Edited by Shayne C. Gad
Copyright © 2013 John Wiley & Sons, Inc.

CYP enzymes, would usually be assessed using the phenotyping approach. Phenotyping for an enzyme—that is, quantification of its actual *in vivo* activity in an individual—is performed by administration of a selective substrate for the enzyme and subsequent determination of appropriate pharmacokinetic metrics closely reflecting enzyme activity.[2] Pharmacokinetic metrics reflecting individual CYP activity best, depending on the individual phenotyping substrate used, may be metabolic ratios of metabolite over parent drug in plasma or urine, clearance of the parent drug, or partial clearance via a specific pathway. It is desirable to use metrics based on a limited number of blood samples. The standard design of respective phenotyping interaction studies is a crossover design with administration of phenotyping agents in both periods, which is combined with coadministration of the therapeutic protein to be tested at its highest chronic therapeutic dose in one period.[2,3]

Concomitant administration of phenotyping substances in a cocktail to test the effects of drugs including therapeutic proteins on several CYPs at a single occasion has been reported extensively.[2,4,5] This approach offers the advantage that the burden for both investigators and volunteers is considerably decreased. In the case of therapeutic proteins, this is especially important because such studies often need to be conducted in patients (discussed later). Beyond the selection of appropriate phenotyping metrics within a phenotyping cocktail, it should be safeguarded that there is no relevant interaction between individual cocktail components.[6] If an interaction between cocktail components cannot be excluded (e.g., chlorzoxazone, a CYP2E1 substrate, is an inhibitor for CYP3A4),[7] it is also possible to split the cocktail, administering the interacting substance on a different day of the study. Tolerability of such drug cocktails is usually excellent because it is possible to select very low doses.[2] Thus the cocktail phenotyping approach is the method of choice for screening for the potential of therapeutic proteins to change CYP activities *in vivo*.

## 7.2 GUIDELINES APPLICABLE FOR COCKTAIL DRUG–DRUG INTERACTION STUDIES

Current regulatory guidelines provide recommendations on individual phenotyping agents.[8,9] Recommended CYP phenotyping agents include CYP1A2, theophylline, caffeine; CYP2B6, efavirenz, bupropion; CYP2C8, amodiaquine, cerivastatin, repaglinide, rosiglitazone; CYP2C9, warfarin, tolbutamide; CYP2C19, omeprazole, esomeprazole, lansoprazole, pantoprazole; CYP2D6, metoprolol, desipramine, dextromethorphan, atomoxetine; CYP2E1, chlorzoxazone; and CYP3A4, midazolam, buspirone, felodipine, lovastatin, eletriptan, sildenafil, simvastatin, triazolam.[8,10] The European Medicines Agency (EMA) list is shorter and more specific. The FDA published an additional list in 2011,[11] presenting substrates considered as sensitive and substrates with a narrow therapeutic range (according to the 1999 document "Guidance for Industry: In Vivo Drug Metabolism/Drug Interaction Studies—Study Design, Data Analysis, and Recommendations for Dosing and Labeling"), which is also incorporated in the 2012 draft guideline.[8,10]

In most cases, several different pharmacokinetic metrics may be used to assess activity of a given CYP. However, the 2010 EMA (draft) guideline on the investigation of drug interactions (CPMP/EWP/560/95/Rev. 1—Corr.[10]) and the updated (draft) FDA guidance[8] request the determination of complete area under the curve (AUC) values of phenotyping substrates. The reason for the reluctance to accept other metrics is that validation is in most cases limited to the quantification of baseline activity in healthy individuals and in the absence of factors with major impact on pharmacokinetics. However, any effects of therapeutic proteins on pharmacokinetic processes may not be limited to the activity of the CYP to be investigated. Additional mechanisms could then be identified by a change in the entire concentration vs. time profile of the phenotyping drug.[3]

Cocktail studies are addressed specifically by the EMA guidance; the FDA standpoint is also available.[8,12,13] The FDA clearly accepts data from cocktail studies. For both agencies, the appropriate composition of a cocktail is a prerequisite.[2] The FDA considers data from cocktail studies to supplement other *in vitro* or *in vivo* information, including physiology-based pharmacokinetic modeling and simulation data. Cocktail studies may also be used to determine the need for further *in vivo* studies. In its most recent (draft) guideline,[8] a further implementation of cocktail studies is supported, and it is mentioned that negative results from cocktail studies may eliminate the need to conduct additional studies. For an investigational therapeutic protein that is a cytokine or cytokine modulator, it is requested that studies should be conducted to determine the effects on cytochrome P450 enzymes (or transporters), and the use of the cocktail approach is mentioned to this end.[8]

## 7.3 COCKTAIL INTERACTION STUDIES WITH THERAPEUTIC PROTEINS: SPECIAL FEATURES

The metabolism and elimination of therapeutic proteins is distinct from that of small molecule drugs, which share metabolism and elimination pathways with most toxic compounds and components of food and environment. Because dietary proteins are predominantly digested in the gut and taken up as amino acids or dipeptides, no particular enzymes or transporters exist for therapeutic proteins. It is therefore unlikely that a therapeutic protein is a substrate of a drug-metabolizing enzyme of phases I and II or of a drug transporter, because the molecules are too large and their structure is not suitable for metabolism or transport by those enzymes and transporters usually encountered in pharmacokinetics. Thus, in general, therapeutic proteins have a lower risk of causing specific metabolic drug interactions mediated by changes in activities of individual enzymes. However, therapeutic proteins may act as modulators of function of these drug-metabolizing and -transporting proteins. Several cytokines, including interleukin 1 (IL-1), IL-6, IL-10, tumor necrosis factor α (TNF-α), and interferon (IFN), have been shown repeatedly to change (usually to downregulate) the expression of various cytochrome P450 enzymes in *vitro*[14–16] and *in vivo*.[17] Accordingly, therapeutic proteins that block the action of such cytokines in pathophysiological processes will also block their effects on drug-metabolizing

enzymes. These cytokine-mediated changes in cytochrome P450 enzyme activities take some time to develop because protein expression is affected. This is in contrast to most enzyme inhibitions by small molecule drugs, which are present almost immediately after the inhibitory drug has been administered, because the underlying mechanism is a direct competitive or a noncompetitive inhibitory interaction with the enzyme itself. Translated to the timing of cocktail dosing this would mean that the administration of the probe substrate cocktail should not take place immediately after the first dose, because the expected effect may require several days and/or repeated dosing until it is fully developed.

Another factor that has to be taken into account is the pharmacokinetics of the therapeutic protein. Because therapeutic proteins are often administered subcutaneously or are chemically modified for increased metabolic stability (e.g., by pegylation) their residence time in the body is often much longer than that of small molecules. Because the therapeutic protein is continuously present in the body for days or even weeks, the effect on drug-metabolizing enzymes and drug transporters may be fully present only after several days or weeks. It is therefore crucial to take the biologic half-life of the compound under investigation into account when the timing of the cocktail-phenotyping days is planned. In addition, it may be wise to consider more than one cocktail-phenotyping day during one treatment course with a therapeutic protein.

Because some therapeutic proteins may cause severe adverse effects, including infections and cancer, their use in healthy subjects is not always justifiable. Thus cocktail interaction studies may need to be conducted in patients. However, such studies in patients may pose major challenges in regard to recruitment of participants, further interactions by concomitant medication, and the variability caused by disease processes. This may also include the amelioration in organ function caused by the therapeutic protein. To give an example, interferons used in the treatment of hepatitis, or therapeutic proteins directed against hepatically metastasizing tumors, may lead to improvements in hepatic function during treatment. This may then also translate into increased activities of CYP enzymes, other drug-metabolizing enzymes, and transporters. Another example is the association between the stage of congestive heart failure, TNF-α and IL-6 concentrations, and their inverse relationship to the activity of the CYP enzyme CYP2C19.[17]

In conclusion, therapeutic proteins may lead to changes in the activities of CYP enzymes by mechanisms different from small molecule drugs. These interactions may take longer to develop (and presumably also longer to subside, but this has not yet been studied), and may also necessitate other designs in cocktail drug–drug interaction studies, particularly because of the long half-life of most therapeutic proteins.

## 7.4 PUBLISHED COCKTAIL INTERACTION STUDIES WITH THERAPEUTIC PROTEINS

In the literature, there are only few drug–drug interaction studies on therapeutic proteins that use the cocktail phenotyping approach, although such an approach has

been endorsed by authors of some review articles in recent years[1,18,19] and by regulatory guidelines on drug–drug interaction studies for drug approval.[8]

A very early example of a cocktail interaction study was carried out with IFN-α in 1993.[20] In that study, a drug cocktail consisting of 150 mg theophylline, 250 mg antipyrine, and 250 mg hexobarbitone was administered to seven cancer patients before, with the first dose, and after 2 weeks of IFN-α dosing. Because these drugs are either no longer in use at all, and/or are not established probe drugs for specific enzymes, the findings are difficult to interpret in terms of generalizability to other drug substrates. The 33% decrease in oral theophylline clearance in this study may be interpreted as a decrease in CYP1A2 activity, the enzyme mainly involved in theophylline clearance; but CYP2A6 may also contribute. Antipyrine is a nonspecific CYP substrate, and the nonsignificant 20–21% decrease in antipyrine clearance both after the first dose and after 14 days of treatment cannot be attributed to a change in a single enzyme activity. Hexobarbitone clearance was unchanged, butbecause hexobarbitone is probably stereoselectively metabolized by various CYP enzymes, the significance of this result remains unclear.

Another, more recent, study investigated the effects of multiple doses of pegylated IFN-α2b on the activities of CYP1A2, CYP2C8/2C9, CYP2D6, CYP3A4/3A5, and *N*-acetyltransferase 2 (NAT2) in 26 patients with chronic hepatitis C infection.[21] The cocktail used in the study consisted of 200 mg caffeine for CYP1A2 phenotyping, 500 mg tolbutamide for CYP2C8/2C9 phenotyping, 45 mg dextromethorphan for CYP2D6 activity assessment, and 100 mg dapsone for the assessment of NAT2 activity, all administered orally and simultaneously, while 4.0 mg midazolam for overall CYP3A phenotyping was administered as a syrup 24 h later. The phenotyping procedures were carried out twice, once before and once after 4 weekly doses of pegylated IFN-α2b adjusted to the body weight of the participants. This cocktail is, according to the authors of the paper, validated but unpublished as "data on file" of the pharmaceutical company that initiated the study. Its composition most resembles the Indianapolis cocktail, with the addition of dapsone as a NAT2 probe substrate, a higher dose of dextromethorphan, and the omission of intravenous midazolam, which is used as a probe for hepatic CYP3A activity.[2]

The authors used appropriate bioequivalence testing methods to calculate point estimates of the geometric means ratios for the selected phenotyping parameters and corresponding 90% confidence intervals. They concluded that multiple doses of pegylated IFN-α2b moderately increased CYP2D6 activity by 67%, but variability was huge (25–123% increase in activity), although genetically poor metabolizers of CYP2D6 had been excluded from study participation. In addition, the authors observed a minor increase in CYP2C8/2C9 activity by 28% (90% confidence interval 15–42%), which was statistically significant but of presumably limited clinical importance, because one border of the 90% confidence interval was within the bioequivalence zone. They did not observe statistically significant changes in overall CYP3A activity and NAT2 activity, but a minimal, but statistically significant decrease in CYP1A2 activity to 92% was noted (90% confidence interval 87–98%).

Since the 90% confidence interval is still entirely within the 80–125% bioequivalence zone, this finding is certainly not clinically relevant.

It is interesting that these findings do not entirely match with the information from studies with pegylated IFN-α2a or IFN-α2b. Namely, CYP2D6 activity is not influenced by pegylated IFN-α2a, while a larger effect on CYP1A2 activity (in the order of a 25% reduction in activity) is mentioned. Possible explanations include the differences in study populations (the present cocktail study was carried out in hepatitis C patients, whereas the studies with IFN-α2a were done with healthy subjects) and an indirect effect mediated by a general amelioration in hepatic function in the patients with chronic hepatitis C by IFN-α2b administration. This study is cited in the U.S. prescribing information, and it is the basis of the precautions for the use of CYP2C9 and CYP2D6 substrates together with pegylated IFN-α2b.

Although this example nicely shows that a cocktail phenotyping study is suitable for the clinical assessment of the relevance of interactions between a therapeutic protein and drug-metabolizing enzymes, there is no other published *in vivo* cocktail interaction study investigating the effect of a therapeutic protein on enzymes and transporters. A search of the U.S. National Institutes of Health clinical study register (www.clinicaltrials.gov) revealed one other cocktail study on the interaction potential of a therapeutic protein. However, that study, which aimed at investigating the effect of briakinumab (ABT-874), a IgG-based monoclonal antibody targeting IL-12/23, was stopped before enrollment, perhaps in the course of the withdrawal of filing of briakinumab at the U.S. and the European medicines agencies because of safety issues. The study was planned to be carried out in patients with plaque psoriasis, the target population for briakinumab, and the scheduled cocktail included caffeine, tolbutamide, omeprazole, metoprolol, and midazolam, for the assessment of the activities of CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4. The cocktail was scheduled to be administered twice, once before, and once 14 days after a single dose of briakinumab.[22]

## 7.5 CONCLUSIONS

In summary, it has been shown that the cocktail approach is suitable for the study of interactions between therapeutic proteins and drugs in humans, namely for the study of the effect of therapeutic proteins on CYP enzyme activities. This is the area in which the FDA's current draft guideline on drug interaction studies recommends the use of cocktail phenotyping studies as an alternative to individual therapeutic protein–drug interaction studies.[8]

# LOGISTIC CONSIDERATIONS IN STUDY DESIGN FOR BIOLOGIC DRUG–DRUG INTERACTION ASSESSMENTS

MIN ZHU and YU-NIEN (TOM) SUN

## 8.1 INTRODUCTION

Evaluation of the drug interaction potential of biologics or therapeutic proteins (TPs) with other TPs or small molecule drugs is an area of emerging research. Different from the pharmacokinetics (PK) drug–drug interaction (DDI) among small molecule drugs in which there are clear mechanisms associated with metabolic pathways mediated by cytochrome P450 (CYP450) enzymes or transporters, there is limited understanding of the mechanistic basis for TP–drug interactions to date. Therefore the design of such interaction studies is challenging in many cases. As described in the literature,[1–3] the common TP elimination mechanisms may include filtration (e.g., into urine), secretion (e.g., into the bile), biotransformation (e.g., catabolism), and target-mediated disposition. Renal elimination, which is one of the primary pathways of small-molecule drugs, is relatively unimportant for large molecules, such as immunoglobin G (IgGs) with a molecular weight of ~150 kDa that prevents efficient filtration through the glomerulus. Secretion into the bile is an important pathway of elimination of IgA antibodies, but this route is not a significant contributor to the elimination of IgG antibodies. The majority of IgG elimination occurs via intracellular catabolism, following fluid-phase or receptor-mediated endocytosis. TP elimination mechanisms distinguish themselves from the hepatic metabolism that is the dominant mechanism for small molecules. In addition, as TPs may be viewed as foreign substances by the body, immune responses that lead to the generation of endogenous antibodies against the TPs may be triggered, which can increase the clearance of TPs.

According to the BIO Survey in 2010, potential TP-DDIs were most evaluated in the therapeutic areas of immunology and oncology.[4] More specifically, TPs as anti-inflammatory agents were often evaluated as potential victims for DDIs. The activities for selected cytochrome P450 enzymes may be altered in the presence of TPs that are cytokines, cytokine modulators, or hormones.[5] Drug- and disease-mediated TP-DDIs have been observed for tocilizumab, which modulates CYP enzymes in patients with rheumatoid arthritis via interleukin 6 (IL-6) specific blockage.[6] It has been demonstrated that methotrexate, an immunosuppressant, will decrease the formation of antidrug antibodies against infliximab and therefore increases its overall exposure.[7] Anticancer TPs were mostly evaluated as potential perpetrators to concomitant medications, particularly for small molecules that are intended to be used in combination therapy and have a narrow therapeutic window (e.g., chemotherapeutics with cytotoxic properties). For example, a DDI evaluation was performed for irinotecan plus bevacizumab in patients with solid tumors, and no significant effect of bevacizumab on the pharmacokinetics of irinotecan or its active metabolite SN38 was observed.[8]

Due to the unique characteristics of biologics in pharmacokinetics and immunogenicity, some design parameters of TP–drug interaction studies are different from those for small molecules. A risk-based drug–drug interaction assessment strategy for TPs should be implemented according to its risk factors and appropriate study designs should be selected.[5,9] The challenges and logistic considerations in study designs for TP–drug interactions are discussed in this chapter.

## 8.2 CHALLENGES IN THE CONDUCT OF A TP–DRUG INTERACTION STUDY

Therapeutic proteins can be roughly divided into two groups according to indications–namely, oncology TPs (for cancer treatment) and nononcology TPs (or rheumatoid arthritis, psoriasis, asthma, prevention of cardiac ischemic complication or other cardiovascular disease). The challenges in the assessment of TP–drug interactions for the two groups of TPs are discussed separately.

In oncology, drug combination (e.g., TP with chemotherapy) is commonly used for the improvement of anticancer activity. With respect to TP–drug interaction assessments, *in vitro* screening–guided drug interaction studies would have limited value because there is often no known underlying mechanism. Furthermore, the TP–drug interaction study is usually not a standalone but rather a substudy of Phase I–III clinical trials conducted in cancer patients in conjunction with efficacy and safety assessments. As a result, conventional well-controlled DDI study conditions (e.g., a controlled diet, comedications, disease status, dose, dosing time, and schedule) are rarely preserved. TP pharmacokinetics data collection is usually less intensive than that for small molecule drug interaction studies. The number of subjects may not be well balanced across treatment cycles or arms, and the number of qualifying subjects is also affected by deviations of scheduled dose and sampling times due to dose interruptions and reductions or patient discontinuations.[10] Challenges

exist in performing noncompartmental pharmacokinetics data analysis because there are often a significant number of data exclusions. Pharmacokinetics assessments are further complicated due to a number of oncology TPs or small molecule drugs exhibiting nonlinear pharmacokinetic properties. Moreover, because a TP-alone arm is uncommon in a drug combination oncology trial, historical data are usually referenced in the TP–drug interaction evaluation either by cross-study comparison or by population pharmacokinetic modeling. Thus a scientifically sound and technically feasible integrated TP–drug interaction evaluation strategy needs to be developed to address these challenges.[11]

In contrast, for nononcology therapeutics such as those in the area of immunology and anti-inflammation, TPs can be used as a monotherapy agent. The concomitant drugs can be randomly prescribed medications for symptom relief or for treatment of other comorbidity conditions according to individual patient's needs. The most documented TP–drug interaction involves an indirect mechanism of cytokine-mediated changes in drug metabolizing enzymes that is secondary to changes in inflammation status. Studies have demonstrated the effect of individual cytokines and their modulators on CYP enzymes and transporters.[6,12–14] In this regard, the TP plays the role of a perpetrator and the small molecule drugs are usually victims. This type of interaction is not solely drug related but also disease related. To date, inflammation- or cytokine-mediated inhibition of CYP activities has become an evolving research area for understanding the mechanism of disease–drug interactions and the associated effect on TP–drug interactions.[15] The challenge in the design of such TP–drug interaction studies is that both the inflammation stage and the concomitant drugs can be moving targets. *In vitro* experiments by using different cytokines and selected animal models at the early stage of drug development may provide some insight into the pharmacokinetic interaction potential for coadministered drugs that mainly undergo the CYP-mediated drug disposition, but the magnitude and clinical relevance of the interaction may still need to be evaluated in the target patient population. A strategy of early establishment of a therapeutic exposure range under TP monotherapy may be important for anti-inflammatory agents to assess extent and clinical significance of changes in drug exposures.

Additional logistic considerations of TP–drug interaction assessments are provided in Table 8-1. Clearly, because the assessment is related to the impact on drug efficacy and safety, early strategy planning is essential to reduce logistic burdens and meet regulatory requirements. The recently released "Draft Guidance for Industry: Drug Interaction Studies–Study Design, Data Analysis, Implications for Dosing, and Labeling" from the FDA, clearly indicates that (1) if an investigational TP is a cytokine or cytokine modulator, studies should be conducted to determine the TP's effect on CYP enzymes or transporters; (2) for TPs that will be used in combination with other drugs as a combination therapy, studies should evaluate the effect of each product on the other; and (3) when there are known mechanisms or prior experience with certain pharmacokinetic or pharmacodynamic interactions, appropriate *in vitro* and *in vivo* assessments for possible interactions should be conducted.[16]

**TABLE 8-1 Logistic Considerations of TP–Drug Interaction Assessment Approach**

| Approach of Assessing TP–Drug Interaction | Pros | Cons |
|---|---|---|
| No evaluation of TP–drug interaction potential | No burden on clinical trial operation and costs | Lack of data to assess potential TP–drug interaction risk and impact on safety and efficacy<br>Lack of data to fulfill regulatory requirements |
| Test of TP–drug interaction potential in healthy subjects | Traditional drug interaction designs and conditions can be applied<br>Low operational burden | Drug combination may not be safe to be tested in healthy subjects (e.g., anticancer drugs)<br>Results may not be applicable to target patient population owing to disease–drug interaction (e.g., anti-inflammatory agents) |
| Estimation of TP–drug interaction in early drug development stage (e.g., Phases I and II) | Data may be used to address potential DDI issue and assist in better design of later stage clinical trials<br>May be executable with limited number of patients and at low cost<br>May identify large signal with an estimation study | Adds some operational burden to clinical trials<br>All tested drugs, including marketed drugs, will be treated as IMPs in Europe and governed by associated regulations<br>Estimation study may not have enough power to identify a mild interaction signal |
| Estimation of TP–drug interaction in late drug development stage (e.g., Phase III) | "No DDI findings for the tested drugs" may be included on a product label | Adds significant operational burden and cost to clinical trials<br>All tested drugs will be treated as IMPs in Europe<br>Study conditions may not be controlled consistently across countries in a global trial<br>Study noise may be increased in a large global trial for detecting a mild interaction signal |
| Dedicated TP–drug interaction study as postmarketing | Study can be powered to address the TP–drug interaction question definitively | Needs an independent study<br>High operational burden and cost to clinical trials |

**TABLE 8-1** (*Continued*)

| Approach of Assessing TP–Drug Interaction | Pros | Cons |
|---|---|---|
| commitment or during drug development | A claim of "lack of TP–drug interaction" may be acceptable on a product label | Patient enrollment may be low owing to intensive PK sample collection and other logistic issues<br>Data evaluability may not be high because of patient dropout and change in dose and regimen owing to side effects (e.g., oncology drugs) |

DDI: drug–drug interaction; IMP: investigational medicinal product; PK: pharmacokinetics; TP: therapeutic protein.

## 8.3 TP–DRUG INTERACTION STUDY DESIGN

Unlike a small molecule drug–drug interaction study in which a two-way drug interaction (i.e., A → B *and* B → A) can be evaluated in the same study, a TP–drug interaction assessment may need to be evaluated as a one-way interaction (i.e., A → B *or* B → A), especially in oncology. Therefore, an important consideration in the design of a clinical TP–drug interaction study is to clearly define the aim of the study and then design the study components accordingly. As mentioned in the previous section, most of the TP–drug interaction studies for oncology and anti-inflammatory therapeutics need to be conducted in patient populations and strictly controlling the potential influential factors (e.g., other comedications, dose and schedule, and disease status) may be challenging. Thus conventional drug interaction study settings generally applicable to most small molecule drugs may not be practical for the TP–drug interaction assessment.

In the oncology research area, because there is no clear mechanism-based TP–drug interaction identified yet, the value of *in vitro* screening and preclinical assessments for guiding a clinical TP–drug interaction study planning has not been well established. To date, inclusion of clinical TP–drug interaction components in Phase I–III studies in patient populations for fixed drug combinations has become a common approach for screening purposes and for identifying if exposures of any drug in a fixed combination are considerably affected, especially for drugs with narrow therapeutic windows. The study is usually performed on a small scale for providing initial data for assessing the risk level of a PK interaction. If a high risk is identified, a confirmative study or formal TP–drug interaction study may be triggered, depending on the clinical relevance of the interaction. This approach appears to be accepted by the regulatory agencies.

In the nononcology research areas, *in vitro* screening and *in vivo* cocktail studies may be applicable for risk assessments at a case-by-case basis. With the *in vitro* evaluation, the impact of cytokines and cytokine modulators on CYP enzymes, mRNA, protein, and activities can be assessed in a concentration-dependent manner. Nevertheless, there are many uncontrolled factors in the experimental conditions, and the *in vitro* system could be donor dependent. Uncertainty of the translatability of nonclinical results to clinical impact may be high.[17] With respect to the *in vivo* cocktail approach, a number of probe drugs for enzymes and transporters can be administered together for simultaneous assessment of interaction between small molecule drugs and TPs.[15] The approach may be efficient for screening TP–drug interaction potential and may be used when no *in vitro* assays can be properly established or for verifying *in vitro* screening results or for planning further clinical assessments. The challenges of this approach may be related to the lack of ideal probe substrates, the validity of cocktail studies, the composition of the cocktails, the extrapolation of results to other drugs, and the differentiation of PK and pharmacodynamic (PD) interactions. Further TP–drug interaction studies may be needed for labeling purposes to provide the magnitude of change in exposure for a particular drug of interest in the cocktail.

With respect to clinical TP–drug interaction assessments, there are at least three types of studies commonly employed–namely, screening studies, estimation studies, and dedicated studies–depending on the purpose of the assessment, phase of clinical development, disease areas, TP–drug interaction risks, and sample size. The pros and cons of these types of study are discussed in the following sections.

### 8.3.1 Screening Study for TP–Drug Interactions

A screening study is usually conducted in patients with a relatively sparse PK sampling scheme to determine if any TP–drug interaction signals are apparent. The study is commonly designed for TPs for which the mechanism of interaction is unknown or an interaction is not expected based on the clearance mechanism of the drugs involved.

The screening study for oncology therapeutics aims at testing the effect of the coadministered drug in a fixed combination with the TP ($D \rightarrow TP$). Sparse TP PK samples are usually collected from all subjects in a trial for evaluating the safety or efficacy while the PK samples of concomitant drugs in the fixed combination are not collected. The TP concentration time data are analyzed preferably via population PK modeling with pooled historical data of monotherapy and the data from the combination study to assess covariate effects of coadministered drugs on the TP clearance. The assessment is feasible in most of clinical trials for screening signals and to check if the TP clearance was considerably affected. If any concerns are raised based on an observed change in drug exposure, additional data analysis may be required, such as including data from additional trials to examine confounding factors because the change in exposure may be the result of not only a TP–drug interaction but also of other factors (e.g., cancer type or disease stage). Besides population PK analysis, summary statistics for comparison of observed TP

concentrations in a drug combination study with those in monotherapy studies are also commonly performed to identify a TP–drug interaction signal. The screening study is usually conducted during Phases I and II trials. Further TP–drug interaction studies may be needed if clinically meaningful changes in TP exposure was to be identified. For nononcology TPs, cocktail studies can be used for screening in order to test the effect of the TP on small molecule drugs (TP → D) because the small molecule drugs are commonly the victims.

### 8.3.2 Estimation Study for TP–Drug Interaction

An estimation study is commonly used for a TP–drug interaction assessment when the mechanism of PK interaction is unknown or the interaction is not expected based on the clearance mechanisms of the drug involved. Unlike a screening study, an estimation study collects PK profiles over a specified interval for concomitantly administrated drugs used in combinations, either for small or large molecule drugs, and relative sparse PK samples (e.g., before and after infusion) for the tested TP. The aim of the study is to evaluate the TP–drug interaction potential with a predefined sample size, which is commonly used for the evaluation of the effect of a TP on coadministered drugs (TP → D). Nevertheless, the sample size for an estimation study is usually 6–15 evaluable subjects per arm, depending on the intersubject variability in drug exposure. This is not a powered study for hypothesis testing. The advantage of this kind of study is to test TP–drug interactions in a small group of patients so the operational challenge is relatively low while it still provides evidence for risk assessment. If remarkable changes in drug exposure are identified, the study data can be used for hypothesis generation and provide valuable information for the design of a formal study. The limitation of this type of study is that the effect of coadministered drugs on TPs (D → TP) may need to be assessed by cross-study comparison or population PK modeling if there is no TP alone arm or testing period in the trials.

### 8.3.3 Dedicated Study for TP–Drug Interaction

The dedicated study for the TP–drug interaction assessment is not frequently conducted for oncology TPs but may be conducted for nononcology TPs. In this type of study, intensive PK samples for both TP and comediations are collected. There is not much difference between the dedicated TP–drug interaction study and the traditional drug–drug interaction study for small molecule drugs except the TP–drug interaction studies are mostly conducted in patient populations to test the effect of drug–disease interactions (e.g., inflammation) or fixed drug combinations (e.g., oncology). The study aims are hypothesis testing with sufficient detection power calculated according to results obtained from a screening study or estimation study. Although this type of TP–drug interaction study can provide confirmative results, the logistic issues are apparent as it usually requires much larger sample size, depending on intersubject variability of TPs, the predefined no-effect boundary, and the rates of evaluable individuals after accounting for patient dropout, dose reduction, and dose interruptions.

## 8.4 TIMING OF TP–DRUG INTERACTION STUDY

The question when to conduct the TP–drug interaction study may be associated with therapeutic areas and the risk level of individual therapeutic proteins. For instance, in the oncology area, it is preferable to include TP–drug interaction assessments in the early Phases I and II trials because this can be the first time that a drug combination is tested, trials are relatively small in size, and operational issues can be addressed easier. It is important that obtaining the interaction data early can help establishing a development strategy and guide later phase study designs. If clinically meaningful interaction signals are identified in early trials, expanded assessments may be further considered. The limitation of early assessments is that the optimal drug combination may be modified in later stages of development or the tested drug combination may not proceed to later phase due to ending of the development program in certain indications. Although it is possible to test TP–drug interactions in late phase studies for product registration, it significantly increases the complexity of pivotal Phase III trials and is thus likely to have more confounding factors and causes difficulty in data interpretation.[10]

In contrast, for TPs for the treatment of immunology- and inflammation-related diseases, most clinical trials in the early phase of clinical development are monotherapy trials. The risk in a change in drug exposure may be from an inflammation-mediated disease–drug interaction rather than a direct TP-mediated PK interaction with randomly prescribed medications. However, because the treatment of inflammation with TPs may affect the magnitude of disease–drug interactions, the treatment-associated TP–drug interaction effect may still need to be monitored if patients are taking narrow therapeutic drugs along with the TPs. Owing to the complexity of the interaction, this type of TP–drug interaction study is not easy to design becuase the extent of interaction could change with treatment and disease status. Standalone trials can be conducted for nononcology TPs by using probe substrates (e.g., midazolam for CYP3A4) to examine the risk level. This type of study is commonly planned in the middle or late phase of development or the postmarketing stage based on clinical significance of effect.

## 8.5 STRATEGIC PLANNING OF TP–DRUG INTERACTION STUDIES

Owing to uncertainties in drug development, strategic planning of TP–drug interaction assessments at the nonclinical, clinical Phases I–III, and postmarketing stages is important for an increase of research effectiveness. A stepwise strategy may be needed for planning purposes, which should be focused on the therapeutic area and specific drug, according to the characteristics of the molecules. To elaborate this, examples for general TP–drug interaction assessment strategies in the oncology and anti-inflammation areas are further discussed.

### 8.5.1 Oncology

The TPs for cancer treatment are frequently used in fixed drug combinations (e.g., with chemotherapy) for enhancement of treatment effect and survival benefit. Because there is no known mechanism-based TP–drug interaction identified to date, either for TPs as victim or perpetrators, the study planning heavily relies on clinical screening with data from both monotherapy and fixed drug combination trials for initial risk assessment. There is no one size fits all strategy in such assessments. Although, there is no clear interaction mechanism, evidence of lack of interaction is still required by regulatory agencies.

The strategy of interaction assessment should be clearly described in a clinical pharmacology plan of an investigational TP at the early phase of drug development. The plan may include the purpose of assessment (e.g., evaluate the TP as a victim or a perpetrator, or both), method of assessment (e.g., population analysis approach, noncompartmental analysis, or a combined approach), criteria of analysis (e.g., what is the clinical significance with a defined magnitude change in exposure?), study planning (alignment in study conditions, sampling strategy, and study population across studies), data integration plan (e.g., identification of studies from which data will be used for the TP–drug interaction evaluation), covariate data collection plan (guarantee that common covariates are collected consistently across studies), communication strategy (alignment with clinical teams), and labeling strategy. It is preferable to collect the TP–drug interaction data in Phases I and II; avoiding Phase II, however, reduces operational challenges. Strategic and systemic planning of TP–drug interaction assessment is important in the oncology area because a cross-study comparison is hardly avoidable, especially for TPs with long half-lives.

For small molecule drugs (e.g., chemotherapy agents) that are commonly used in combination with TPs for cancer treatment, it would be useful to establish an integrated internal database across different oncology programs for effectively using all available data.[18] For instance, it is common that selected chemotherapy backbone treatments (e.g., paclitaxel, cisplatin) are tested repeatedly for the same or similar indications (e.g., lung and colon cancers) for different investigational TPs. However, the sample size of each trial might be small (e.g., $n = 5$–7 evaluable subjects) owing to operational difficulties, and missing samples are common because patients are unable to go back to clinics to have blood drawn and often have dose delays or reductions. Therefore, it would be useful to collect PK data of a specific chemotherapy agent with a standardized sample collection scheme for all oncology programs and the data from the control arms (e.g., paclitaxel backbone cohort) of each study in the same patient population may be combined for data analysis to increase detection power and establish a no-effect boundary for a test agent.[19,20]. The established exposure range can be used for all other relevant studies in which the agent was included in drug combinations.

For TPs, PK data will be collected from most subjects, thus sample size will not be an issue. As a result of rare standalone drug interaction trials, TP monotherapy data, usually collected in the first-in-human study, need to be included in the data analysis. It is important to predefine a no-effect boundary as a reference exposure range for

each drug in a drug combination based on pharmacokinetics, safety, and efficacy information. If the exposures in the testing cohort were within the ranges, lack of TP–drug interaction effect may be claimed. Otherwise, a detailed covariate analysis will be performed to identify if the change in exposure is owing to a TP–drug interaction or nondrug interaction factors (e.g., cancer type, disease stage, biomarker related subpopulation). If there is clear evidence that the change in exposure is due to nondrug interaction factors, lack of TP–drug interaction may be claimed. If the change in exposure could be the result of a TP–drug interaction and the magnitude of change may have a clinical consequence, further evaluation may be considered. All evaluation results of different TP–drug combinations in a TP development program can be summarized to provide an overall picture of interaction potential for an investigational TP. The results of the TP–drug interaction assessment via planned analysis should be provided on the drug product label with a detailed description of how data were collected and analyzed. This approach may be applicable not only to oncology TPs but also to nononcology TPs that have no clear mechanism of interaction.

### 8.5.2 Immunology and Inflammation

In contrast, in nononcology areas, such as immunology and anti-inflammation, the TPs are frequently used as monotherapy. Although *in vitro* screening and *in vivo* cocktail approaches may be useful for initial risk assessment, clinical studies under actual treatment conditions in target populations will provide more convincing evidence. Because drugs mainly metabolized by CYP enzymes may be affected by the disease–drug interaction, adequate recording of concomitantly used drugs over a sufficiently long period (e.g., >6 months) may provide some evidence for assessing risk of TP–drug interactions. Covariate analysis via population PK modeling is commonly used for identifying the interaction signals with the individually prescribed and long-term used comedications.[15] If a significant effect is identified and change in exposure may have a clinical consequence, further evaluation of a drug interaction may be considered.

## 8.6 CONSIDERATIONS IN STUDY DESIGN

### 8.6.1 Study Population

In drug–drug interaction studies for small molecules, it is acceptable to conduct the study in healthy subjects because the purpose of the study is to evaluate the direct effect of one drug on the disposition of another concomitantly administered drug for which drug metabolism and elimination pathways may be affected. However, the assessment of oncology TP–drug interaction is rarely conducted in healthy subjects owing to safety considerations. In the immunology therapeutic area, because inflammation-mediated disease–drug interaction governs the mechanism of TP–drug interaction, the target patient population has to be evaluated to assess the magnitude of disease–drug interaction over time. As a result, the conduct of TP–drug interaction studies in target patient populations is appropriate in most cases.

### 8.6.2 Selection of Interacting Drugs

The selection of interacting drugs for investigation is mainly based on the potential of concomitant usage, PK, and PD properties and the therapeutic window of the selected drugs. For instance, if an investigational TP will be used in a combination of two chemotherapy agents and one supportive hormonal agent, and the hormone drug has a wide safety window and is prescribed at a low dose, the selected testing drugs for the interaction study can be the TP and the two chemotherapy agents. In the inflammation area, because each patient may be taking his or her own long-term medications along with the TP treatment, the drugs with narrow therapeutic windows will be the choice of probe drugs for the assessment. The primary consideration in drug selection should be based on the drug elimination mechanism.

### 8.6.3 Type of Study Design

The parallel design and the one-sequence crossover are the commonly selected study designs in TP–drug interaction evaluations (Figure 8-1). The design should be chosen based on the PK properties of the TP and coadministered drugs as well as the potential interaction mechanism.

**FIGURE 8-1** Examples of (a) one-sequence crossover and (b) parallel designs. D: small molecule drug; PK: pharmacokinetics; TP: therapeutic protein; WK: week.

The one-sequence crossover (sequential) design is common for testing the effect of a TP on a small molecule drug (TP → D), such as administration of a chemotherapy agent (D) on day 1 and TP on day 2 in one cycle followed by administration of both D and TP on day 1 in a cycle at steady state (Figure 8-1a). Each subject serves as his or her own control to minimize variability and allow for the achievement of sufficient statistical power with a reasonable sample size.

Examples exist for the evaluation of two-way interactions of both TP and small molecule drugs with one sequence crossover design in a single study. In oncology, a study was conducted for the evaluation of the interaction between trastuzumab and paclitaxel in which paclitaxel was administered alone in cycle 1 to collect paclitaxel concentrations, followed by paclitaxel coadministration with trastuzumab with assessment of PK profiles of both drugs in cycle 4, and then trastuzumab monotherapy in cycle 10 or beyond for collection of trastuzumab-alone concentration data.[21] In the inflammation area, the interaction between digoxin and etanercept was assessed with a one-way, crossover, three-period design (digoxin → digoxin + etanercept → etanercept).[22]

The sequential one-way crossover study is ideal for short-half life ($t_{½}$) drugs (e.g., hours) and TPs (e.g., a few days). The advantage of this design is that the study requires fewer subjects when compared to that with parallel design. A limitation of this type of study is that it requires longer study duration so that it may be suitable only for patient populations that have long life expectancy. However, if patients drop out from the study for any reason, imbalanced patient numbers over the study period may occur, which will affect the study evaluation and power of assessment. Moreover, this type of study cannot avoid a sequence effect, especially when dose interruption occurs, and it cannot be used to evaluate the effect of D → TP if there is no TP-alone arm or testing period in the study. In this case, a cross-study comparison for TP exposure needs to be made.

Many TP products have long half-lives (weeks) as well as nonlinear PK owing to target-mediated clearance, or they form antiproduct antibodies that may alter their own clearance. These unique TP characteristics produce unavoidable sequence effects that preclude the use of the crossover designs for assessing TP–drug interaction effects. More complicated studies can be designed to assess the sequence effect. As an alternative for avoiding the sequence effect, parallel designs can be considered for the TP–drug interaction assessments.

A parallel design includes two arms (Figure 8-1b), one for examining drug exposures when administered alone and the other for examining drug exposures in the presence of TP. When a TP has a relative long half-life (10–20 days) and patients have relative short life expectancy (< 6 months, with end stage cancer), this type of design may become the only choice for the drug interaction assessment. Intensive PK samples are usually collected in the first cycle of treatment rather than at steady-state owing to the short life expectancy of the patients. Sparse PK samples can be collected continuously in the following cycles for examining drug accumulation and steady-state concentrations.[18] The study is more appropriate for Phase II oncology studies in which chemobackbone is included in a positive control arm. PK samples of chemotherapy agent from both arms can be collected to compare

exposures with and without the TP. The assessment of effect of chemotherapy on TP may need a cross-study comparison by either noncompartmental analysis (NCA) or population PK modeling owing to lack of a TP alone arm in the same study.

When the TP elimination half-life is relatively short, it is possible to evaluate TP → D and D → TP effects with a parallel design in a single study. This was demonstrated in an interaction study between cetuximab ($t_{½} = 5$ days) and irinotecan ($t_{½} < 1$ day). In this study, two test groups were designed in parallel. Group A was to test the effect of cetuximab on the PK of irinotecan, in which irinotecan was administered alone followed by the drug combination. Group B was to test the effect of irinotecan on the PK of cetuximab in which cetuximab was administered alone followed by the drug combination.[23]

The advantage of the parallel design is the study duration is relatively short when compared to the crossover design, and it is relatively easy to randomize patients in the parallel arms to minimize bias in patient selection owing to baseline characteristics. There is no sequence effect for this type of design, and the design is commonly used to examine TP–drug interaction effects for D + TP and TP + TP combinations in either open-label or double-blind studies. The disadvantage of the design is that much more patients are needed, especially for highly variable TPs, to achieve the same detection power as with the crossover design.

A hybrid approach with a one-way sequential design for a Phase Ib study (e.g., chemo followed by chemo + TP, open label) staggered with a double-blind parallel design in the Phase II portion of the study for testing the effect of TP on chemotherapy is not uncommon in oncology trials.[10] The study is more appropriate for Phase Ib/II trials in which insufficient data on chemotherapy are collected in the Phase Ib portion and the data will be continuously collected in the Phase II portion. The assessment of the effect of chemotherapy on TP may still need a cross-study comparison.

### 8.6.4 Regimen Selection

In oncology, because TPs are commonly used as add-on therapy, the regimen of the backbone treatment (e.g., chemotherapy or target therapy) becomes an important determining factor for the choice of regimen. For instance, the TP regimen will be once every 3 weeks (Q3W) for the treatment of lung cancer if coadministered paclitaxel is given Q3W. On the other hand, if a small molecule drug is given daily, then the regimen of TP can be flexible (e.g., QW, Q2W, Q3W), according to the half-life of the TP and the safety and efficacy profiles. In immunology, in which TPs are frequently used as monotherapy, the choice of regimen is mainly based on the PK, efficacy, and safety profiles of the TP.

### 8.6.5 Sampling Scheme

Depending on the PK characteristics of the tested drugs, intensive PK samples that enable assessment of the AUC of the tested drugs are usually collected for drugs

with short half-lives, and relatively sparse PK samples are collected for TPs owing to their much longer half-lives. Combined sampling schemes–for example, collection of intensive sampling in cycle 1 and sparse sampling at steady state–are common for TPs. Population PK modeling and simulation can be used to optimize sampling schemes. To evaluate the clinical relevance of change in drug exposure parameters, samples for safety, pharmacodynamics, and efficacy measures may be collected along with the concentration samples. If an interaction was observed, clinical relevance of the interaction can be evaluated in conjunction with safety and efficacy data for supporting data interpretation.

### 8.6.6 Endpoints for TP–Drug Interaction Evaluation

The peak ($C_{max}$) and trough ($C_{min}$) concentration are common PK endpoints for TPs in TP–drug interaction assessment when only sparse concentration data are collected. With intensive concentration sample collection and model-based data analysis, the AUC and clearance can be the estimated exposure and PK parameters. Because intensive PK samples can be collected for small molecules, $C_{max}$, $C_{min}$, and AUC are the commonly estimated exposure endpoints. The most relevant exposure parameters should be the ones associated with safety and efficacy events. If a TP–drug interaction signal is observed, an assessment based on a joint evaluation of PK, safety, and efficacy data should be the primary consideration in data interpretation.

### 8.6.7 Sample Size

For a screening TP–drug interaction study, sample size can be $< 10$ subjects per arm, with intensive sampling for small molecule drugs and several hundred subjects with sparse sampling for TPs. All subjects with relevant data can be included in the data analysis. For an estimation study, the TP–drug interaction evaluation is usually performed with 10–20 patients per arm in a PK subgroup assessment of clinical trials. The sample size of fully powered TP–drug interaction studies for hypothesis testing is much larger, depending on power of detection, intersubject variability in TP exposure (e.g., CV = 30–50%), and the preset criteria of no-effect boundary.

### 8.6.8 Criteria for TP–Drug Interaction Evaluation

One of the important aspects in strategic planning and perspective study design is to predefine acceptable criteria of no-effect boundary. Prior knowledge and literature information from molecules with similar structures and elimination mechanisms will be valuable for developing the acceptable clinical criteria. In fact, experience in development of such criteria is very limited for TPs so far. It requires collective knowledge of the disease, comorbidities, cytokine levels under physiological and disease conditions, immunogenicity, biological target, pharmacology of the molecules, PK and PD of involved drugs, and the various mechanisms involved in the

TP clearance. Accumulation of such knowledge on a continuous basis will help properly establish the criteria.[11]

For small molecule drugs, the nominal 80–125% criterion is commonly accepted for no-effect boundary of parameter estimates. However, if the same criterion is applied to TPs, a larger sample size is needed not only because of the large intersubject variability in TP exposures but also because of the studies needed to be conducted in patients in the outpatient setting. In oncology, for instance, patients participate in PK evaluation voluntarily. They may not come to clinics for a blood draw according to protocol-specified time as a reslut of individual difficulties. Data are commonly missed; changes of dosing schedule and reduction of dose levels may be needed for management of adverse events. These factors may lead to an increase in the number of unevaluable subjects so that an extra subjects are need to make up for unpredictable events.

In the TP–drug interaction assessment, the no-effect boundary may be considered to be slightly larger for TPs (e.g., 70–143%) than that for small molecule drugs if it is clinically justifiable. Eventually the determining factors for the acceptable criteria should be associated with the therapeutic window established for the drugs of interest.

## 8.7 DATA ANALYSIS

A data analysis approach is closely related to the study design. For dedicated TP-DI studies, intensive PK samples are collected in a sufficient number of subjects. Noncompartmental analysis (NCA) is the primary data analysis method, which is straightforward, makes few assumptions, and is accepted by regulatory agencies. For screening and estimation TP-DI studies, depending on the sampling scheme and number of subjects with evaluable samples, both NCA and population PK modeling approaches as well as a combination of the two approaches may be applied. For the prospectively designed Phase IIb or Phase III studies with DDI components, the primary analysis approach is population PK modeling. Each analysis approach has advantages and limitations, which are discussed in the following sections.

### 8.7.1 Noncompartment Analysis

As mentioned, the NCA method is simple, descriptive, less resource constrained, and widely accepted by regulatory agencies. Therefore it should be the first choice when intensive PK samples are collected. This is especially true when an interaction study is conducted in healthy subjects. However, when a TP–drug interaction study is conducted in patients, whether this method is still applicable depends on the number of evaluable samples collected in a dosing interval and whether the original sampling scheme is closely followed. If the preset dosing conditions have been greatly modified, it would be difficult to provide summary statistics and make reasonable comparisons to assess the interaction effect. In such cases, the population PK modeling approach will be more appropriate for further analyzing the data.

### 8.7.2 Population Pharmacokinetic Modeling

The great advantages of the population PK modeling approach may include the following:

- The method is less affected by sampling conditions and dose modifications and interruption.
- Data from different trials can be combined to increase detection power and accuracy of parameter estimation and provide a comprehensive evaluation of interaction potential for drugs of interest.
- Both sparse and intensive PK data can be used, and multiple covariates can be evaluated at the same time.
- The magnitude of multiple covariate effects on drug exposure or clearance can be ranked, thus the effect contributed by coadministered drugs can be quantified.
- The effect on drug metabolite(s), if any, in the TP–drug interaction can be further evaluated.

The effect of one drug on the other is usually assessed as a covariate of drug clearance. The method is able to differentiate the effect of a coadministered drug from other factors (e.g., baseline characteristics, demographics, lab values, biomarkers, disease status, etc.) if sufficient information is available. With combination of efficacy and safety data, a PK-PD model can be further established for the evaluation of the clinical relevance of such an effect. The model is used not only to describe observed data but also to simulate data under untested study conditions and for an improved design of the next interaction studies (e.g., to select an optimal sampling scheme and to overcome operational difficulties). The simulation may help evaluate logic of dosing schedules for coadministered drugs to minimize the interaction. Model-based simulations with a large number of subjects may increase the confidence of the analysis.

Concerns of using population PK analysis may include the following:

- The modeling approach makes assumptions and may not be accepted by all regulatory agencies around the world.
- It requires much longer time or more resources for data analysis when compared to NCA.
- When there are too few data and parameter estimates have a large uncertainty, the modeling result may be inconclusive.
- The interaction assessment may be affected if dosing records for tested TP and coadministered drugs are incomplete.
- The interaction effect may be underestimated or overestimated when using sparse data pooled from multiple studies and when certain study factors are imbalanced across studies.

- Studies generating PK data were not designed for the drug interaction assessment, thus the evaluation results may be considered as exploratory.

The lack of a signal can occur if the studies are underpowered to detect the interaction signal. Therefore, the modeling approach will be best used when the study is designed for an interaction evaluation, and potential confounding factors are controlled as much as possible.

## 8.8 PROSPECTIVELY DESIGN OF TP–DRUG INTERACTION STUDY

The screening and estimation types of TP–drug interaction studies, as mentioned in the early part of this chapter, are exploratory in nature for hypothesis generation. The findings may need to be confirmed, especially when changes in drug exposure have potential clinical impact. It is possible to prospectively design the interaction study so that the evaluation results can be considered as confirmatory from the statistical perspective.

The analysis approach requires (1) establishing a model structure for the drug of interest with historical monotherapy data with incorporation of prior knowledge, (2) simulation of concentration-time profiles based on conditions set in the TP interaction study protocol, (3) analysis of the simulated data with the established model and making adjustments in the model structure if needed (the sample size of the study needs to be reasonable, which will be estimated based on the number of subjects in each arm, number of samples per subject, and variability in drug exposure), (4) the selected model structure and no-effect boundary of drug exposure need to be prespecified in the data analysis section of the protocol or in the related statistical analysis plan, and (5) the analysis of the data from the prospectively designed interaction with the prespecified model and examination if the observed data fall within the expected concentration range. Additional sensitivity analysis and ad-hoc analysis may be performed based on the outcomes of analysis. If the observed data are within the specified concentration range, lack of interaction can be confirmed. If significant interaction is observed, the clinical relevance of the effect will be further evaluated in conjunction with assessments of efficacy and safety data. A publication on how to perform confirmatory analysis with population PK modeling is recommended for further reading.[24]

## 8.9 SUMMARY

Assessment of TP–drug interactions is an emerging research area of clinical pharmacology. The logistic considerations in conducting a TP–drug interaction study are being realistic and being practical. The FDA is currently revising its NDA and Biologics License Application (BLA) recommendations to industry sponsors to recognize the accumulation of TP–drug interaction experiences.[5,16] The current guidance does acknowledge the challenges associated with the use

of *in vitro* and *in vivo* data for assessing the risk of TP–drug interactions as well as the design and conduct of such studies. Scientific investigation in this emerging area is needed to improve study design and analysis methods. Prospectively designing TP–drug interaction studies with integrated data analysis may improve the power of detection and reduce certain operational challenges. A further understanding of the mechanisms of TP–drug interaction is needed to better design studies and to ensure patient safety.

# STATISTICAL CONSIDERATIONS IN ASSESSING DRUG–DRUG INTERACTIONS FOR THERAPEUTIC BIOLOGICS

CHUANPU HU and HONGHUI ZHOU

## 9.1 INTRODUCTION

Therapeutic biologics have different mechanisms of action from small molecules, usually making drug–drug interactions (DDIs) less likely, although this may depend on the specific circumstances. That is, the *a priori* expectation of specific DDIs is different with therapeutic biologics. In addition, therapeutic biologics usually have long half-lives, preventing the effective use of the usual crossover trials to assess drug–drug interactions. These issues influence the design and analysis of DDI assessments. Furthermore, population pharmacokinetics modeling has been used increasingly in drug development and has promising potential in DDI assessment. This chapter discusses the associated statistical issues, particularly to ensure appropriate power and type I error.

DDIs can adversely affect the safety or efficacy of a treatment. Therefore a new drug's DDI potential needs to be fully assessed. Namely, the objective is to obtain estimates of AUC and $C_{\max}$ ratios of interest and their corresponding 90% confidence intervals (CIs). The 90% CIs falling within a predetermined interval–for example, (0.80, 1.25)–indicates the absence of a pharmacokinetic DDI. Dedicated DDI study designs may be the conventional $2 \times 2$ crossover, single sequence crossover, or parallel designs. A specifically selected sequence of *in vitro* and *in vivo* studies can generally define a new experimental drug's clinically relevant DDI potential. The FDA has published a draft guidance on the design and analysis of DDI studies.[1] While AUC assessments are the mainstay of DDI studies, $C_{\max}$ is not assessed in all situations.

Therapeutic biologics often have long elimination half-lives of up to 3 weeks, making conventional crossover studies with adequate washout periods difficult to conduct.[2] A single sequence crossover study with the investigated therapeutic biologic added to the second period is still possible, but a potential confounding time effect cannot be excluded. Some other unique challenges of designing and conducting DDI studies of therapeutic biologics were acknowledged by the FDA draft guidance. For example, classical biotransformation studies are not required routinely, and *in vitro* metabolism-based interactions studies are not generally predictive. On the other hand, there is a concern for the appropriate assessment of metabolic DDIs involving certain biologics, such as type I interferons that inhibit CYP1A2.[3]

There is not yet a uniformly accepted approach regarding DDI assessments for therapeutic biologics. Ideally, an integrated risk assessment should be made in consideration of existing data and knowledge, and clinical relevance. Important factors include therapeutic target, therapeutic window, and mechanisms of drug action.[4]

Population pharmacokinetics (PK) modeling is a powerful tool to synthesize multiple sources of information, including occasional sparse data, to assess PK along with its between-subject variability and to determine the influence of covariates. Because concomitant medication is a type of covariate, population PK can also be used for DDI assessments. It has special appeal in light of the difficulties of conducting conventional DDI studies for therapeutic biologics and has been used in multiple drug development programs.[5–16]

The methodology of population PK is still evolving, along with its applications. The FDA guidance document acknowledged its benefits in assessing DDI, and emphasized the importance of the associated study design and analysis planning. Most applications adopt the exploratory approach where multiple forms of structural, between-subject and within-subject variability models are attempted and one final, best-fitting model is chosen. Conclusions are then based on the final model. In principle, the exploratory approach is hypothesis generating, and the findings need to be confirmed later. While $p$-values may be generated, they are for the purpose of selecting the final model and do not have the appropriate original statistical interpretation of type I error (i.e., false positive rates). On the other hand, it is often desirable for DDI assessment to be confirmatory, especially in regulatory settings. That is, evidence of DDI, or the lack thereof, needs to be quantifiable with controllable type I error. Using population PK modeling in this setting requires special considerations.[17] In the following sections, the necessary theory is introduced along with an example for its application.

## 9.2 METHODOLOGY FOR DRUG–DRUG INTERACTION ASSESSMENTS

### 9.2.1 Conventional DDI Assessment

The statistical methodology for assessing DDI is based on that for bioequivalence. The most common purpose of bioequivalence assessments is to evaluate the

comparability of bioavailability of several drug formulations. Standard bioequivalence studies are $2 \times 2$ crossover studies, and subjects are densely sampled so that individual PK exposure parameters, AUC and $C_{max}$, can be determined with precision. These individual PK parameters are then log-transformed to be used with standard models, adjusting for sequence and period effects, to obtain a 90% confidence interval of log(test/reference ratio). The confidence interval is then back-transformed to the original scale to obtain the confidence interval for the test/reference ratio of average PK parameters. Confidence intervals falling within (0.80, 1.25) indicate bioequivalence. For the statistical theory, see Ref. 18 for details.

DDI studies assess the influence on pharmacokinetics by other drugs instead of formulation effects. Such studies are usually single-sequence crossover or parallel studies, but the assessment method remains the same–that is, whether the confidence intervals of AUC and $C_{max}$ ratios fall within (0.80, 1.25). Of resemblance are PK similarity assessments between subject populations (e.g., healthy volunteers vs. patients). The single-sequence design is more convenient than the $2 \times 2$ crossover, although it faces the theoretical risk that a potential period effect may confound the DDI effect. The parallel design is the most convenient, but in addition to the risk of confounding period effect, it also requires larger sample sizes due to uncontrolled between-subject variability.

Testing whether the DDI effect is significant is not appropriate. The FDA draft guidance states that "because small . . . differences can be statistically significant ($p < 0.05$), but not clinically relevant." There is also a further reason to this–namely that inadequate sample sizes can result in statistically insignificance even though the real effect is clinically relevant.

Preliminary testing—that is, testing the statistical significance of some terms such as period or sequence effect to decide whether to include them in the analysis model—is generally not conducted. This would result in poor statistical behavior of the overall test owing to correlation between the preliminary test and the final test.[19]

### 9.2.2 Population Pharmacokinetics Based DDI Assessments

Population PK has been used for DDI assessment, typically by assessing a drug interaction effect on clearance (CL) or apparent CL.[6–15] Statistical significance of, for example, a DDI effect on CL, has been used on occasion as the deciding criterion; however, this is not appropriate for the same reason as with traditional DDI assessments. The current FDA draft guidance also discourages the use of this simplistic statistical significance criterion by stating: "Population analyses should focus on excluding a specific clinically meaningful PK change." In some other instances, empirical Bayesian individual parameter estimates (e.g., for CL) have been used; however, this is also inappropriate because the individual estimates suffer from shrinkage and are not independent.[20,21]

The appropriate population PK based DDI assessment should be performed as follows: Under the PK model, the effect of the interacting drug on any model parameter can be determined along with 90% CI. Specifically, let $\theta$ be the

parameter, CL, and $\theta_i$ be the parameter value of the $i$th subject, and $X_i = 0$ or 1 be the indicator of whether subject $i$ has the concomitant medication, and $\beta$ represents the DDI effect. The parameter estimate of $\beta$, along with its 90% CI, can be obtained. The DDI effect is most commonly modeled as

$$\theta_i = \beta^{X_i}\theta \tag{9-1}$$

with constraint $\beta > 0$, or

$$\theta_i = (1 + \beta X_i)\theta \tag{9-2}$$

with constraint $\beta > -1$.

Usually, a DDI effect on AUC can be considered the same as that on CL or apparent CL owing to the relationship AUC = Dose/CL.

A DDI effect on $C_{\max}$, if needed, can be determined from the DDI effect on model parameters, at least in theory. In practice, this may be most easily done by reparameterizing the model and using $C_{\max}$ as a parameter. For example, in an intravenous (IV) one-compartment model with a single dose, the DDI effect on $C_{\max}$ can be considered the same as that on volume $V$ owing to the relationship $C_{\max}$ = Dose/$V$. Then, the model can be reparameterized using ($K_a$, AUC, $C_{\max}$) instead of ($K_a$, $V$, CL). If reparameterization cannot be easily done (e.g., for two- or three-compartment models with first-order absorption), the assessment can be done using the bootstrap analysis outlined later in the chapter.

It is possible to obtain an approximate sense of the sample size needed.[22] Simulation is a general option that can be used to assess sample size and design characteristics.[23]

***9.2.2.1 Similarity and Difference between Traditional and Population PK Based Assessments*** In principle, the traditional method assesses the drug interaction effect on the geometric means of AUC and $C_{\max}$, whereas the population PK based model assesses the drug interaction effect on the population average effect. The relationship between the geometric means and the population average AUC and $C_{\max}$ therefore deserves elaboration.

Commonly used population PK models assume between-individual variability of CL as log-normally distributed, which implies that the geometric mean AUC in the population equals the AUC of the average individual.[17] Likewise, under the commonly used assumption of the central volume $V$ being lognormally distributed, the geometric mean $C_{\max}$ in the population (approximately) equals the $C_{\max}$ of the average individual for IV dosing regimens. However, no such general conclusions for $C_{\max}$ holds under oral or subcutaneous (SC) dosing regimens, regardless of distributional assumptions for the rest of the PK parameters.[20] In such situations, the computation of $C_{\max}$ depends on all other model parameters. Unlike for CL, in most situations no single model parameter would amount to the drug-interaction effect on $C_{\max}$.

Obtaining the average $C_{max}$ from population PK models with absorption terms is difficult, because the distribution of $C_{max}$ usually cannot be directly calculated from the between-subject variability distribution of model parameters. Despite the difference, there is no *a priori* reason to prefer the geometric means, and assessing the drug interaction effect on the $C_{max}$ of the average individual, as computed from the estimated population PK model parameters, is reasonable.[20]

***9.2.2.2 Confidence Interval Construction under Population Pharmacokinetic Modeling*** Given a population PK model and data, estimates of DDI effects and the corresponding 90% CIs can be computed.

A simple way to obtain the 90% CI of a DDI effect β is to use its estimate β′ and standard error SE(β′), as

$$(\beta' - \Phi(0.95) * \mathrm{SE}(\beta'),\ \beta' + \Phi(0.95) * \mathrm{SE}(\beta'))$$

where Φ is the cumulative standard normal distribution, and $\Phi(0.95) \approx 1.645$. This involves a normal approximation that, in theory, requires that β is parameterized on the scale $(-\infty, +\infty)$. Therefore, using the following parameterization of the DDI effect β

$$\theta_i = \exp(\beta)^{X_i}\theta \tag{9-3}$$

instead of Eq. 9-1 or 9-2 can make the normal approximation more tenable. If estimation is precise–that is, SE(β′) is small relative to β—the difference between using Eq. 9-3 vs. Eq. 9-1 or 9-2 will be small.

The standard errors of parameter estimates from nonlinear mixed-effect models are approximate, not exact. Bootstrap is an alternative method for generating standard errors and CIs of parameter estimates.[24] It is often believed to be more accurate, although some evidence suggests that it behaves similarly as the standard errors of parameter estimates.[25,26] In the case that the DDI effect on $C_{max}$ needs to be assessed but cannot be formulated as a model parameter, assessment based on standard error of parameter estimate is not possible. However bootstrap can still be used, because in each bootstrap run, the predicted $C_{max}$ with and without the interacting drug, and thus their ratio, can be calculated from the population model parameters.

*Bootstrap Confidence Interval Construction* Bootstrap can be used to generate 90% CIs by the percentile bootstrap method, which uses the 5% and 95% percentiles of the bootstrap runs. Specifically, in each bootstrap run, a bootstrap data set can be generated in which the subjects were resampled with replacement. Parameter estimates can be obtained for the bootstrap data set, and thus a ratio of AUC and $C_{max}$ can be determined. Results of all bootstrap runs can be assembled and the 5% and 95% percentiles used to construct the 90% bootstrap confidence intervals. In general, bootstrap results are also approximate, and the precision depends on whether the numbers of subjects in the resampled categories (i.e., studies) are large

enough to properly represent the entire population. In addition, the following issues are important for its implementation:

*Stratifications.* More stratification variables usually lead to more similar bootstrap datasets and thus narrower CIs. Therefore the proper level of stratification needs to be maintained to ensure correct statistical interpretations. The principle of bootstrap relies on the assumption that the resampling distribution correctly represents the true population distribution. This implies that, in general, design factors, and only design factors should be chosen as stratification factors. For example, *study* should always be a stratification factor–that is, the respective numbers of subjects in each study from a multistudy dataset should be kept unchanged. A more complex and subtle factor is the ratio of subjects with and without the interacting drug in each study. Often it is not a design variable and therefore should not be stratified. However if the study had been included in the DDI analysis because it has a particular ratio of subjects with and without concomitant medication, then the ratio should be a stratification variable. It may happen when all design factors are stratified, as they should be, the number of subjects within some strata becomes too small to accurately represent the population distribution. This is a potential limitation to bootstrap use.

*Number of bootstrap runs to conduct.* This may depend on the desired precision and the type of data, and thus is difficult to say in general. It has been suggested that at least 2000 samples may be needed.[24] In the authors' experience, 2000–5000 will generally suffice.

*Which bootstrap runs to include.* It may be argued that the runs that "failed" in certain ways (e.g., unable to converge or provided standard errors, parameter estimates near boundary) should be excluded. On the other hand, such failed runs correspond to data that are more likely to be atypical, such as at the tail ends of the distribution. In estimating the 90% confidence interval, these types of samples are of particular interest, and runs need to be restarted until convergence is achieved. A counterargument to restarting the failed runs is that the successful runs were not paid similar attention, thus the bias, if any, caused by ignoring failed runs may not be so severe. It may also be argued that when the software converges successfully but fails to produce standard error of parameter estimates, it presents only an algebraic problem unrelated to the quality of convergence and thus, such runs should be included. The problem can be alleviated, to a certain extent, by using multiple starting estimates for each run to improve the convergence rate. A conservative solution may be to include all runs. Future investigations are necessary to determine how to best deal with failed runs.

***9.2.2.3 Influence of Model Searching on DDI Effect Assessment*** The use of population PK requires the selection of a population PK model, which consists of three components: a structural model, a variability model (for both between-subject and within-subject variability), and a covariate model. Influences of these

components on DDI assessments are elaborated in the subsections below. Most applications of population PK were conducted using the exploratory approach, which selects the model that best fits the data among the many possible alternative models, either explicitly or implicitly. While this approach has intuitive appeal, the inferences drawn from the final selected model do not possess statistical validity.[20] Even though at times some hypothesis tests may be conducted, they are generally used as a tool for model selection. Because the model and hypothesis tests are not prespecified, the associated p-values and CIs are not statistically interpretable. The source of the problem is similar to that of the earlier mentioned preliminary testing in bioequivalence (BE) analyses. Further reasons that model exploration may adversely affect DDI analysis include overfitting and selection bias.[27–30]

In theory, inferences could appropriately be made by including the model search into the considerations. For example, bootstrap could be done by including the entire model search process instead of only the final selected model. This has not been described yet, but this argument shows that model search usually leads to increased uncertainty in the results.

*Influence of Structural Model on DDI Effect Assessment* The AUC (and thus the ratio of with to without interacting drug) estimate should be relatively robust because models usually represent the average concentration reasonably well. For $C_{max}$, however, the opposite is true, because fitting simpler structural models to the same data generally leads to smaller $C_{max}$ estimates. Therefore, a simpler model is more likely to bias the DDI assessment of $C_{max}$ toward lack of DDI. This argument could be extended to say that any population PK model will likely underestimate $C_{max}$ because the reality is always more complex. This may be true, but these findings should be placed into perspective. The traditional use of measured $C_{max}$ also underestimates the true $C_{max}$, because $T_{max}$ may not be among the sampling times. A practical prerequisite of using population PK is that sufficient data are available to describe the absorption process.

*Influence of Random Effect Model on DDI Effect Assessment* The within-subject random effect model, also called residual error model, has the effect of weighting concentration measurements differently during the model fitting. Commonly used models are the additive-plus-proportional, proportional, and lognormal model,[29] which take the form as following, respectively:

$$y = p + p * \varepsilon_1 + \varepsilon_2 \tag{9-4}$$

$$y = p + p * \varepsilon_1 \tag{9-5}$$

$$\log(y) = \log(p) + \varepsilon_1 \tag{9-6}$$

where $y$ is the observed concentration, $p$ is model prediction, and $\varepsilon_1$, $\varepsilon_2$ are independently normally distributed. These, in increasing order, weigh smaller concentrations more. Therefore model (9-4) may result in a $C_{max}$ estimation closer to

observed data than models (9-5) and (9-6). Choice among these models, especially between models (9-6) and (9-5), is still of much debate, and currently there is no consensus on which one to use. It may be prudent to base the choice on the type of assay and prior experience with the class of compounds.

Other models have occasionally appeared in literature, at times selected by goodness-of-fit criteria, but caution is necessary. For example, the log-likelihoods of model (9-5) and (9-6) have been compared, which is not statistically meaningful. Another example lies in the attempted approach to combine models (9-4) and (9-5), which takes the form of

$$\log(y) = \log(p) + \varepsilon_1 + \log(p) * \varepsilon_2.$$

This form has the variance of the total residual error on the log scale at the minimum when the prediction $p = 1$, which is difficult to justify. Yet another example has a type of hybrid residual error model as

$$\log(y) = \log(p) + \sqrt{\varepsilon^2 + \varepsilon^2/p^2}$$

This model has the property that, as the prediction approaches zero, the variance approaches infinity. This is also difficult to justify, especially when predose concentration measurements suggest limited variability. Inappropriate residual error models may lead to biased estimation of $C_{\max}$ and AUC.

Many between-subject random effect model parameters, such as correlations among random effects, are of limited interest in DDI assessment. In theory, there is no value to formally test them because there is no *a priori* reason that they should not exist, and any statistical insignificance would only be due to the lack of power to detect the effects. However, it seems plausible that including such effects could cost degrees of freedom and may dilute the power for assessing DDI effects. We suggest that such terms are not included, especially in situations in which power is lacking, pending further investigation.

*Influence of Covariate Models on DDI Effect Assessment* The influence of including additional covariate effects (e.g., gender) in a population PK model is discussed here. In traditional DDI assessments of standard crossover studies, adjusting for gender has no effect because each subject serves as his or her own comparison. Including gender in a population PK assessment for DDI is analogous to adjusting for gender in BE assessments of parallel studies, which adds one term to the linear model and costs only one degree of freedom but can potentially improve the error estimate and thus improve the power of the DDI assessment. However, in population PK modeling it is less clear where to add the gender effect, unless prior information is available. Adding gender influence to all model parameters not only reduces more degrees of freedom but also increases the complexity of parameter estimation. Bootstrap analyses could be particularly sensitive to model instability, because a large number of model runs are needed and convergence could become

problematic. Furthermore, casual correlations between gender and interacting drug usage, if present, can also confound DDI assessments.

In general, the statistical behavior of an analysis becomes worse the more exploration is allowed.[19,28] Intuitively, more model exploration would adversely affect the power of concluding the similarity of PK, because some degrees of freedom must be sacrificed for exploration. The issue would be much more apparent if an exploratory analysis had arrived at some exotic model, such as one that had ethnic origin influence absorption rate that is both weak from its pharmacological mechanism and numerically unstable.

***9.2.2.4 Confirmatory Population Pharmacokinetic Modeling for DDI Assessments*** A confirmatory population PK approach has been recently proposed that achieves the appropriate inferences by prespecifying the analysis model based on available information and the analysis objective.[30,31] The quality of the confirmatory analysis will clearly depend on the suitableness of the prespecified model for the DDI analysis. At most stages of the DDI analysis, data from prior Phase I and II studies are available and provide good information about the PK structural and variability models and even information for some relevant covariates, such as weight. Depending on the analysis objective, all components of the model do not have to be "correct" to yield appropriate results.[29] For example, assessing DDI effects on CL is often robust to model misspecification of between-subject random effect components on the absorption rate constant in a one-compartment model with first-order absorption.[30,32]

Typical steps of DDI assessments using confirmatory population PK in Phase III studies involve the following:

1. *Determine which DDI effects need to be assessed based on mechanistic rationale and whether the sample size is sufficient.* The sample size needed for a reasonably precise determination of the effect size depends on the number of subjects with and without the concomitant medication, along with the number of PK concentration measurements and PK between- and within-subject variability.
2. *Prespecify the population PK structural and variability models based on available information and current Phase III study design.* This can frequently be done by using a previously built population PK model using data from Phases I and II to simulate datasets under the current Phase III study design. Model exploration may be used at this time on the simulated data to see what choice of the structural model, variability model, or even limited covariate models, such as weight can be best supported from the current Phase III study design. The model most stable under the simulated data can be used as the population PK analysis model for the DDI assessment. Most often, a one-compartment model will be selected. As the observed PK concentration data of the current Phase III study have not been used to select the model, they are prespecified and thus the analysis is confirmatory.

3. *Prespecify the covariate model.* Most often, the concomitant medication effects are on clearance. Mechanistically meaningful covariates based on prior information should be retained, such as weight on clearance and volume when existing in the previously built population PK model.
4. *Prespecify sensitivity analyses.* Alternative competing assessments, if needed. Such analyses, if conducted at all, should be limited, given the confirmatory objective.
5. *Determine the magnitude of a relevant DDI effect.* For example, try 70–143%. Determine the power of the DDI assessment accordingly, likely through simulations, and assess only those DDI effects that have sufficient power. If a clear criterion cannot easily be determined, the rule of thumb of at least 20 subjects per effect estimated might suffice, and the resulting 90% CIs may be compared with the nominal 80–125% criterion.

Some of the above steps, especially 1–3, are interrelated and should perhaps be better viewed as one joint step with multiple components. Step 5, determining the criterion of DDI, affects the power assessment but not the assessment method, thus it may be less crucial in practical implementations For further details, see Ref. 29.

In rare situations unexpected complexities may arise, including substantial noncompliance or model nonconvergence. Deviations from the prespecified model would be necessary in these situations to deal with such irregularities but should be maintained at a minimal level and should stay true to the principle of the prespecified analysis.

Because of the many assumptions, a population PK model, whether prespecified or obtained by exploratory search, is unlikely to be "true." However, the relevant question for most applications of modeling is never whether the final model is right or wrong. As has been repeatedly quoted, "All models are wrong, but some are useful." The focus should be on the DDI assessment results instead of on the model–that is, the purpose of the analysis is to obtain not the best description of the data but the most credible estimates along with the associated standard errors for DDI effects.

### 9.2.3 Comparison between Traditional and Population PK Based DDI Assessments

The traditional and the population PK approaches have different advantages. The traditional assessment employs fewer assumptions, is robust to model misspecification, better protects against type I error, and is easy to interpret. The population PK approach can be used in situations not originally designed for DDI assessments, such as, Phase III studies, and to incorporate information from multiple sources by using meta-analyses. A population PK assessment based on large Phase III studies also may better reflect the DDI effect in actual clinical practice. However, population PK is more complex in methodology and thus requires more expertise in design, analysis, and evaluation stages. Data/design quality (e.g., variability in

actual dose/sampling times) may adversely affect study power. However this should not affect type I errors and thus presents only a sponsor risk.

## 9.3 POPULATION PHARMACOKINETICS FOR DRUG–DRUG INTERACTION ASSESSMENTS: USTEKINUMAB

An example of using confirmatory population PK for DDI assessments in phase III clinical studies is described in the following. Ustekinumab is a human monoclonal antibody that binds with high specificity and affinity to the shared p40 subunit of IL-12 and IL-23 and blocks interaction with the IL-12Rβ1 cell surface receptor. The pharmacokinetic properties of ustekinumab have been well characterized after single-dose SC administration (0.27–2.7 mg/kg) and single-dose intravenous administration (0.1–5.0 mg/kg) in patients with psoriasis. The PK of ustekinumab was linear over the wide dose range studied.

***9.3.1.1 Study Design*** Data from two large Phase III trials of ustekinumab in patients with moderate to severe psoriasis (PHOENIX 1 and PHOENIX 2) were used for the DDI assessment.[33,34] Both were multicenter, randomized, double-blind, placebo-controlled, parallel design studies. The study designs were complex, and consisted of placebo-controlled, placebo crossover, dose optimization, randomized withdrawal, and long-term extension periods. Briefly, in PHOENIX 1, a total of 766 patients were assigned to receive SC injections of ustekinumab 45 mg, ustekinumab 90 mg, or placebo at weeks 0 and 4, followed by active treatment every 12 weeks or placebo crossover to ustekinumab 45 mg or 90 mg starting at week 12 (weeks 12–40), followed by randomized withdrawal (weeks 40–76). In PHOENIX 2, a total of 1230 patients were assigned to the same treatment groups and design until week 28, followed by dose schedule optimization (weeks 28–52). Blood samples for the measurement of serum ustekinumab concentrations were collected at weeks 0, 4, 12, 16, 24, 28, 40, 44, 48, and 52 in PHOENIX 1 and at weeks 0, 4, 12, 16, 20, 24, and 28 in PHOENIX 2. At visits when patients received the study agent, blood samples were collected prior to study agent administration. A validated electrochemiluminescent immunoassay method, with a lower limit of quantification of 0.17 μg/mL at a minimum required 1 : 10 dilution, was used to measure serum ustekinumab concentrations. Multiple covariates were collected in the trials, including demographics and concomitant medications.

### 9.3.2 Confirmatory Population Pharmacokinetic Analysis Plan

Several key elements were considered in deciding the covariates to be included in the analysis. These include inherent pharmacokinetic behavior, intended indication and patient population, intended product label, and anticipated important/relevant covariates as learned from similar or related molecules. Before beginning the analysis, a list of the covariates to be included was developed based on physiological relevance, pharmacological importance, baseline disease severity and/or status,

geographic location, past use of relevant medications, relevant concurrent comorbidities, and most commonly used concurrent medications. The following covariates were included: weight, immune response (positive/nonpositive), age (<65 vs. ≥65 years), sex, race (Caucasian, Black, Asian, other), creatinine clearance, geographic region, past use of biologics (yes/no), past use of methotrexate (yes/no), past use of cyclosporine (yes/no), duration of disease, baseline disease scores (PASI), baseline physician global assessment score, baseline dermatology quality index, diabetes status (yes/no), hypertension history (yes/no), lipidemia history (yes/no), alcohol history (yes/no), smoking status (yes/no), and the following concomitant medicines: amlodipine, atenolol, atorvastatin, hydrochlorothiazide, lisinopril, metoprolol, ramipril, metformin, citalopram, and influenza vaccine. The list was developed with the assurance that at least 20 subjects were available for each covariate effect parameter estimated. The exact numbers of subjects who had the concomitant medications were 67, 69, 61, 140, 110, 74, 57, 76, 46, and 106, respectively.

The following analysis plan and rationale were specified before beginning the analysis on observed concentrations.

*Base structural, random-effect and covariate model.* A previous population PK model based on a combined prior Phase I/II dataset was available, with a structural model of a one-compartment model with extravascular absorption. It had between-subject variance on absorption rate constant ($K_a$), apparent clearance (CL/F) and apparent volume of distribution ($V/F$), and an additive-plus-proportional residual error model. In addition, CL/F was proportional to weight raised to the power of 0.75 and $V/F$ proportional to weight. This model was used to simulate data with the actual dosing information and sampling times in the Phase III studies. The best random-effect structure was developed from the simulated data, based on the usual fitting criteria. Base-model exploration on simulated data showed that, as expected, between-subject random-effect on $K_a$ could not be identified. Influence of weight on CL/$F$ and $V/F$ was deemed estimable. Therefore, the prespecified base model had between-subject random effects on CL/$F$ and $V/F$ and also weight effects on them, with an additive-plus-proportional residual error model.

*Covariate model and DDI assessments.* The full model consisting of the covariates listed was used on CL/$F$ only. That is, no covariate models were used on $V/F$ or $K_a$.

### 9.3.3 Covariate and Drug–Drug Interaction Effect Assessment

The prespecified model was implemented with NONMEM (version VI, level 1, ICON Development Solutions, Ellicott City, MD). Model estimation was stable. The parameter estimates and their associated standard errors were used to compute the 90% CIs for all covariate effects on CL/$F$, including the concomitant medications. The 90% CIs are plotted in Figure 9-1. All concomitant medication effects had 90% CIs within (0.8, 1.25), therefore the lack of DDI was concluded for them.

**FIGURE 9-1** The 90% confidence intervals (CI) of covariate and concomitant medication effects. CL: apparent clearance; CrCL: creatinine clearance; PASI: Psoriasis Area and Severity Index score; PGA: Physician's Global Assessment score.

The confirmatory population PK approach gave statistically appropriate 90% CIs for all covariate effects on CL/F, including the concomitant medications.

## 9.4 SUMMARY

DDI assessments for therapeutic biologics have unique challenges. Conventional DDI assessment is still the most robust and least controversial approach. Although it can be inconvenient to conduct, risk-based approaches can be used to guide the assessment. In contrast, the population PK approach has the ability to integrate information from multiple sources, and its potential in DDI assessment has yet to be fully utilized. Adopting the confirmatory approach ensures methodological appropriateness and increases the confidence in its conclusions. The population PK approach may be most useful when AUC is the main focus. The methodology of population PK is still evolving, and special attention needs to be paid to fulfill the objectives of DDI assessments and maintain statistical appropriateness. In principle, population PK assessment should fully parallel the traditional assessments, both in prespecifying the analysis model and ensuring sufficient study design and sample size.

# SCIENTIFIC PERSPECTIVES ON THERAPEUTIC PROTEIN DRUG–DRUG INTERACTION ASSESSMENTS*

HONG ZHAO, LEI ZHANG, KELLIE REYNOLDS, and SHIEW-MEI HUANG

## 10.1 INTRODUCTION

Many intrinsic and extrinsic factors can affect an individual patient's drug exposure and response.[1] The FDA has published a number of guidance documents that recommend how and when to evaluate these factors during drug development.[2] The most recent FDA draft guidance on drug interactions[3] provides advice for *in vitro* and *in vivo* drug interaction studies, including suggestions for study design, dosing strategies, data analysis and interpretation, and the type of information that should be included in medical product labels; it updates the FDA's recommendations on the evaluation of important cytochrome P450 enzyme- and transporter-based drug interactions, and the use of physiologically based pharmacokinetic modeling approaches for drug interaction assessment; and it expands recommendations on therapeutic protein–drug interaction assessment. The recommendations are illustrated via a series of decision trees. This draft guidance and other FDA publications related to drug–drug interactions (DDIs),[4–8] including the website *Drug Development and Drug Interactions*,[9] provide recommendations on how to evaluate drug interaction potential for both small molecules (drugs or Ds) and therapeutic proteins (TPs).

Two review papers published in 2007 contain examples of drug interactions involving TPs.[10,11] Several recent publications summarize the TP-DDI evaluation included in Biologics License Application (BLA) submissions and current strategies for the evaluation of TP-DDI potential during drug development.[12–17]

*The views expressed in this book chapter are those of the authors and do not necessarily reflect the official views of the US Food and Drug Administration.

The purpose of this chapter is to describe our review of the literature on drug interactions involving TPs, the FDA's expanded recommendations on TP-DDIs in the updated draft drug interaction guidance, and FDA-approved product labels that include TP-DDI information. The information presented in this chapter includes the following:

- TPs with drug interaction studies conducted during product development
- Types of study designs used to evaluate TP-DDIs
- Impact of study results on product label

## 10.2 THERAPEUTIC PROTEIN–DRUG INTERACTION STUDIES

Therapeutic proteins are increasingly being combined with small-molecule drugs and/or with other TPs to gain greater clinical benefit. Our survey of 76 new molecular entity TPs that were approved by the FDA up to February 2010 examined drug interaction information in product labels to help determine the types of TPs for which drug interaction studies are informative (Table 10-1).[14] The survey showed that 44 TPs (58%) included some information on drug interactions in the label (including 9 with dedicated TP-DDI studies). The products most likely to have drug interaction information in the label were therapeutic cytokines (9/11, 81%), followed by therapeutic monoclonal antibodies (mAbs), some of which are cytokine modulators (19/29, 66%). Some cytokines are involved in the pathophysiology of various human diseases and are produced during infection and inflammation. Therapeutic cytokines are used in the treatment of certain diseases such as cancer. Various *in vitro* and limited *in vivo* human studies indicate that cytokines and cytokine modulators can differentially influence the expression or activities of specific cytochrome P450 (CYP) enzymes and/or drug transporters through multiple mechanisms[18–23] and therefore have the potential to alter the systemic exposure and/or clinical response of concomitantly administered drugs that are substrates for the

affected CYP enzymes or transporters. For example, therapeutic mAbs that modulate cytokine activities can indirectly influence the expression of specific CYP enzymes and drug transporters by affecting cytokine concentrations.[24,25] Examples of TPs that affect CYP enzymes are listed in Table 10-2. In addition, the exposure to therapeutic mAbs can be altered by concomitantly administered immunosuppressive drugs that affect the formation of antiproduct antibodies.[26,27]

TP-drug interactions (either pharmacokinetics [PK] or pharmacodynamic [PD] based) have been observed, and information about these interactions is included in product labeling (Tables 10-3 and 10-4).[26] The FDA's recommendations on the evaluation of DDIs involving small molecule drugs, including study design, data analysis, and dosing and labeling implications have been described in detail.[4–9] Many of the same principles apply to the evaluation of DDI involving TPs. The current thought process for evaluation of TP-DDIs and the types of studies that have been conducted during drug development to evaluate TP-DDI interactions are illustrated in Figure 10-1.[3] General considerations are discussed below:

- If an investigational TP is a cytokine or cytokine modulator that has known effects on CYP enzymes or transporters, studies should be conducted to determine the magnitude of the TP's effects on drugs that are substrates of the affected CYP enzymes or transporters[13,19]

  *In vitro* and *in vivo* studies have been conducted to determine the TP's effects on CYP enzymes or transporters. When the TP is a cytokine modulator, the effects of both the specific cytokine(s) being modulated and the cytokine modulator on enzymes and transporters may be assessed using *in vitro* models (such as human hepatocytes with the addition of a physiologically relevant

**TABLE 10-2 CYP Enzymes with Decreased Activities (Unless Noted) in the Presence of Specific Cytokines, Cytokine Modulators, and Human Growth Hormone Based on *In Vitro* and/or *In Vivo* Human Studies[a]**

| CYP Enzyme | Cytokines/Cytokine Modulators |
|---|---|
| CYP1A2 | IFNα, IFNα-2b, IFNβ, IL-2, IL-6, hGH[b] |
| CYP2C8 | IL-1 |
| CYP2C9 | IL-2, IL-10 |
| CYP2C19 | Tocilizumab,[c] IFNα-2b, IFNβ, IL-2, TNFα, IL-6, hGH |
| CYP2D6 | IFNα-2b |
| CYP2E1 | IL-2, IFNα-2b |
| CYP3A | Basiliximab, muromonab-CD3, tocilizumab,[c] IL-1, IL-2, IL-6, IL-10 |

[a]Modified from Ref. 13; data from Refs. 14 and 20. All have data from *in vitro* and *in vivo* studies in humans to support the changes in cytochrome P450 (CYP) enzyme activities and/or expression with the exception of human growth hormone (hGH), interleukin 10 (IL-10), muromonab-CD3, and basiliximab, for which only *in vivo* data are available.
[b]The effect of hGH is increased activity.
[c]The effect of tocilizumab, an IL-6 receptor inhibitor, is increased activity.
IFN: interferon; TNF: tumor necrosis factor.

**TABLE 10-3 Examples of Labeling Language for Therapeutic Protein–Drug Interactions (Pharmacokinetic-Based)**

| TP Name<br>(Brand Name)<br>Pharmacologic Class<br>Year of Labeling | Item | Labeling Language |
|---|---|---|
| 1. CYP enzyme modulation by cytokines and cytokine modulators | | |
| Interferon α-2a<br>(Roferon-A)<br>INF-α<br>2006 | Precautions: drug interactions | Roferon-A has been reported to reduce the clearance of theophylline. The clinical relevance of this interaction is presently unknown.<br>α-Interferons may affect the oxidative metabolic process by reducing the activity of hepatic microsomal cytochrome enzymes in the P450 group. Although the clinical relevance is still unclear, this should be taken into account when prescribing concomitant therapy with drugs metabolized by this route. |
| Peginterferon α-2a<br>(Pegasys)<br>INF-α<br>2011 | Highlights of prescription information: drug interactions | *Drugs metabolized by CYP1A2*: monitor for increased serum levels of theophylline and adjust dose accordingly. (§7.2)<br>*Methadone*: monitor for signs and symptoms of methadone toxicity. (§7.3) |
| | 4 Contraindications | Pegasys/Copegus combination therapy is additionally contraindicated in combination with didanosine. Reports of fatal hepatic failure and peripheral neuropathy, pancreatitis, and symptomatic hyperlactatemia/lactic acidosis have been reported in clinical trials. (§7.4) |
| | 7 Drug interactions | |
| | 7.1 Drugs metabolized by cytochrome P450 | There was no effect on the pharmacokinetics of representative drugs metabolized by CYP 2C9, CYP 2C19, CYP 2D6 or CYP 3A4.<br>Treatment with Pegasys once weekly for 4 weeks in healthy subjects was associated with an inhibition of P450 1A2 and a 25% increase in theophylline AUC. |
| | 7.2 Theophylline | Treatment with Pegasys once weekly for 4 weeks in healthy subjects was associated with an inhibition of P450 1A2 and a 25% increase in theophylline AUC. Theophylline serum levels should be monitored and appropriate dose adjustments considered for patients given both theophylline and Pegasys. |

| | | |
|---|---|---|
| | 7.3 Methadone | In a PK study of HCV subjects concomitantly receiving methadone, treatment with Pegasys once weekly for 4 weeks was associated with methadone levels that were 10–15% higher than at baseline. The clinical significance of this finding is unknown; however, patients should be monitored for the signs and symptoms of methadone toxicity.<br>The PK of concomitant administration of methadone and Pegasys were evaluated in 24 Pegasys naive cCHC subjects (15 male, 9 female) who received 180 μg Pegasys SC weekly. All subjects were on stable methadone maintenance therapy (median dose 95 mg, range 30 mg to 150 mg) before receiving Pegasys. Mean methadone PK parameters were 10–15% higher after 4 weeks of Pegasys treatment compared to baseline. Methadone did not significantly alter the PK of Pegasys compared to a PK study of 6 cCHC subjects not receiving methadone. |
| Interferon α-2b<br>(Intron A)<br>INF-α<br>2011 | Precautions: drug Interactions | Interactions between Intron A and other drugs have not been fully evaluated. Caution should be exercised when administering Intron A therapy in combination with other potentially myelosuppressive agents such as zidovudine. Concomitant use of INF-α and theophylline decreases theophylline clearance, resulting in a 100% increase in serum theophylline levels. |
| Peginterferon α-2b<br>(PEG-INTRON)<br>INF-α<br>2011 | Highlights of prescription information: drug interactions | *Drug metabolized by CYP450*: caution with drugs metabolized by CYP2C8/9 (e.g., warfarin, phenytoin) or CYP2D6 (e.g., flecainide). (§7.1)<br>*Methadone*: monitor for increased narcotic effect. (§7.2) |
| | 7 Drug Interactions | |
| | 7.1 Drugs metabolized by cytochrome P450 | When administering PEG-INTRON with medications metabolized by CYP2C8/9 (e.g., warfarin and phenytoin) or CYP2D6 (e.g., flecainide), the therapeutic effect of these substrates may be decreased. (§12.3). |
| | 7.2 Methadone | PEG-INTRON may increase methadone concentrations. (§12.3). The clinical significance of this finding is unknown; however, patients should be monitored for the signs and symptoms of increased narcotic effect. |

(*continued*)

**TABLE 10-3** (*Continued*)

| TP Name (Brand Name) Pharmacologic Class Year of Labeling | Item | Labeling Language |
|---|---|---|
| | 12 Clinical Pharmacology | |
| | 12.3 Pharmacokinetics: drug interactions | |
| | Drugs metabolized by cytochrome P450 | The pharmacokinetics of representative drugs metabolized by CYP1A2 (caffeine), CYP2C8/9 (tolbutamide), CYP2D6 (dextromethorphan), CYP3A4 (midazolam), and *N*-acetyltransferase (dapsone) were studied in 22 subjects with CHCwho received PEG-INTRON (1.5 μg/kg) once weekly for 4 weeks. PEG-INTRON treatment resulted in a 28% (mean) increase in a measure of CYP2C8/9 activity. PEG-INTRON treatment also resulted in a 66% (mean) increase in a measure of CYP2D6 activity; however, the effect was variable: 13 subjects had an increase, 5 subjects had a decrease, and 4 subjects had no significant change. (§7.1) |
| | | No significant effect was observed on the pharmacokinetics of representative drugs metabolized by CYP1A2, CYP3A4, or *N*-acetyltransferase. The effects of PEG-INTRON on CYP2C19 activity were not assessed. |
| | Methadone | The pharmacokinetics of concomitant administration of methadone and PEG-INTRON were evaluated in 18 PEG-INTRON-naive CHC subjects receiving 1.5 μg/kg PEG-INTRON SC weekly. All subjects were on stable methadone maintenance therapy receiving ≥40 mg/day before initiating PEG-INTRON. Mean methadone AUC was approximately 16% higher after 4 weeks of PEG-INTRON treatment compared to baseline. In 2 subjects, methadone AUC was approximately double after 4 weeks of PEG-INTRON treatment compared to baseline. (§7.2). |
| Tocilizumab (Actemra) Human IL-6 receptor blocker 2011 | 7 Drug interactions 7.2 Interactions with CYP450 substrates | Cytochrome P450s in the liver are downregulated by infection and inflammation stimuli, including cytokines, such as IL-6. Inhibition of IL-6 signaling in RA patients treated with tocilizumab may restore CYP450 activities to higher levels than those in the absence of tocilizumab, leading to increased metabolism of drugs that are CYP450 |

substrates. *In vitro* studies showed that tocilizumab has the potential to affect expression of multiple CYP enzymes, including CYPlA2, CYP2B6, CYP2C9, CYP2C19, CYP2D6 and CYP3A4. Its effect on CYP2C8 or transporters is unknown. *In vivo* studies with omeprazole, metabolized by CYP2C19 and CYP3A4, and simvastatin, metabolized by CYP3A4, showed up to a 28% and 57% decrease in exposure 1 week after a single dose of Actemra, respectively. The effect of tocilizumab on CYP enzymes may be clinically relevant for CYP450 substrates with narrow therapeutic index, where the dose is individually adjusted. On initiation or discontinuation of Actemra, in patients being treated with these types of medicinal products, therapeutic monitoring of effect (e.g., warfarin) or drug concentration (e.g., cyclosporine or theophylline) should be performed and the individual dose of the medicinal product adjusted as needed. Prescribers should exercise caution when Actemra is coadministered with CYP3A4 substrate drugs when a decrease in effectiveness is undesirable (e.g., oral contraceptives, lovastatin, atorvastatin.). The effect of tocilizumab on CYP450 enzyme activity may persist for several weeks after stopping therapy. (§12.3).

12 Clinical pharmacology
12.3 Pharmacokinetics: drug interactions

*In vitro* data suggested that IL-6 reduced mRNA expression for several CYP450 isoenzymes, including CYPlA2, CYP2B6, CYP2C9, CYP2C19, CYP2D6, and CYP3A4, and this reduced expression was reversed by co-incubation with tocilizumab at clinically relevant concentrations. Accordingly, inhibition of IL-6 signaling in RA patients treated with tocilizumab may restore CYP450 activities to higher levels than those in the absence of tocilizumab, leading to increased metabolism of drugs that are CYP450 substrates. Its effect on CYP2C8 or transporters (e.g., P-gp) is unknown. This is clinically relevant for CYP450 substrates with a narrow therapeutic index, where the dose is individually adjusted. On initiation of Actemra, in patients being treated with these types of medicinal products, therapeutic monitoring of the effect (e.g., warfarin) or drug concentration (e.g., cyclosporine or theophylline) should be performed and the individual dose of the medicinal product

(*continued*)

**TABLE 10-3** (*Continued*)

|---|---|---|
| | | adjusted as needed. Caution should be exercised when Actemra is coadministered with drugs where decrease in effectiveness is undesirable, such as oral contraceptives (CYP3A4 substrates). (§7.2). |
| | Simvastatin | Simvastatin is a CYP3A4 and OATPlBl substrate. In 12 RA patients not treated with Actemra and receiving 40 mg simvastatin, exposures of simvastatin and its metabolite, simvastatin acid, was 4- to 10-fold and 2-fold higher, respectively, than the exposures observed in healthy subjects. One week following administration of a single infusion of Actemra (10 mg per kg), exposure of simvastatin and simvastatin acid decreased by 57% and 39%, respectively, to exposures that were similar or slightly higher than those observed in healthy subjects. Exposures of simvastatin and simvastatin acid increased upon withdrawal of Actemra in RA patients. Selection of a particular dose of simvastatin in RA patients should take into account the potentially lower exposures that may result after initiation of Actemra (due to normalization of CYP3A4) or higher exposures after discontinuation of Actemra. |
| | Omeprazole | Omeprazole is a CYP2C19 and CYP3A4 substrate. In RA patients receiving 10 mg omeprazole, exposure to omeprazole was approximately twofold higher than that observed in healthy subjects. In RA patients receiving 10 mg omeprazole, before and 1 week after Actemra infusion (8 mg per kg), the omeprazole $AUC_{inf}$ decreased by 12% for poor ($n = 5$) and intermediate metabolizers ($n = 5$) and by 28% for extensive metabolizers ($n = 8$) and were slightly higher than those observed in healthy subjects. |

| | | |
|---|---|---|
| | Dextromethorphan | Dextromethorphan is a CYP2D6 and CYP3A4 substrate. In 13 RA patients receiving 30 mg dextromethorphan, exposure to dextromethorphan was comparable to that in healthy subjects. However, exposure to its metabolite, dextrorphan (a CYP3A4 substrate), was a fraction of that observed in healthy subjects. One week following administration of a single infusion of Actemra (8 mg per kg), dextromethorphan exposure was decreased by approximately 5%. However, a larger decrease (29%) in dextrorphan levels was noted after Actemra infusion. |
| Rilonacept (Arcalyst) IL-1β blocker 2008 | 7 Drug interactions<br>7.2 Cytochrome P450 substrates | The formation of CYP450 enzymes is suppressed by increased levels of cytokines (e.g., IL-1) during chronic inflammation. Thus it is expected that for a molecule that binds to IL-1, such as rilonacept, the formation of CYP450 enzymes could be normalized. This is clinically relevant for CYP450 substrates with a narrow therapeutic index, where the dose is individually adjusted (e.g., warfarin). On initiation of Arcalyst, in patients being treated with these types of medicinal products, therapeutic monitoring of the effect or drug concentration should be performed and the individual dose of the medicinal product may need to be adjusted as needed. |
| Canakinumab (Ilaris) IL-1β blocker 2012 | 7 Drug interactions<br>7.3 Cytochrome P450 substrates | Interactions between Ilaris and other medicinal products have not been investigated in formal studies.<br>The formation of CYP450 enzymes is suppressed by increased levels of cytokines (e.g., IL-1) during chronic inflammation. Thus it is expected that for a molecule that binds to IL-1, such as canakinumab, the formation of CYP450 enzymes could be normalized. This is clinically relevant for CYP450 substrates with a narrow therapeutic index, where the dose is individually adjusted (e.g., warfarin). On initiation of canakinumab, in patients being treated with these types of medicinal products, therapeutic monitoring of the effect or drug concentration should be performed and the individual dose of the medicinal product may need to be adjusted as needed. |
| Golimumab (Simponi) TNF blocker | 7 Drug interactions<br>7.4 Cytochrome P450 substrates | The formation of CYP450 enzymes may be suppressed by increased levels of cytokines (e.g., TNF-α) during chronic inflammation. Therefore, it is expected that for a |

(*continued*)

| TP Name (Brand Name) Pharmacologic Class Year of Labeling | Item | Labeling Language |
|---|---|---|
| 2011 | | molecule that antagonizes cytokine activity, such as golimumab, the formation of CYP450 enzymes could be normalized. On initiation or discontinuation of Simponi in patients being treated with CYP450 substrates with a narrow therapeutic index, monitoring of the effect (e.g., warfarin) or drug concentration (e.g., cyclosporine or theophylline) is recommended and the individual dose of the drug product may be adjusted as needed. |
| Infliximab (Remicade) TNF blocker 2011 | 7 Drug interactions 7.5 Cytochrome P450 substrates | The formation of CYP450 enzymes may be suppressed by increased levels of cytokines (e.g., TNF-α, IL-1, IL-6, IL-10, IFN) during chronic inflammation. Therefore, it is expected that for a molecule that antagonizes cytokine activity, such as infliximab, the formation of CYP450 enzymes could be normalized. On initiation or discontinuation of Remicade in patients being treated with CYP450 substrates with a narrow therapeutic index, monitoring of the effect (e.g., warfarin) or drug concentration (e.g., cyclosporine or theophylline) is recommended, and the individual dose of the drug product may be adjusted as needed. |
| Ustekinumab (Stelara) human IL12/IL23 antagonist 2012 | 7 Drug interactions 7.3 Cytochrome P450 substrates | Drug interaction studies have not been conducted with Stelara. The formation of CYP450 enzymes can be altered by increased levels of certain cytokines (e.g., IL-1, IL-6, IL-10, TNFα, IFN) during chronic inflammation. Thus, STELARA®, an antagonist of IL-12 and IL-23, could normalize the formation of CYP450 enzymes. Upon initiation of STELARA® in patients who are receiving concomitant CYP450 substrates, particularly those with a narrow therapeutic index, monitoring for therapeutic effect (e.g., for warfarin) or drug concentration (e.g., for cyclosporine) should be considered and the individual dose of the drug adjusted as needed [*see Clinical Pharmacology (12.3)*]. |

| | | |
|---|---|---|
| | 12 Clinical pharmacology | |
| | 12.3 Pharmacokinetics: drug–drug interactions | The effect of IL-12 or IL-23 on the regulation of CYP450 enzymes were evaluated in an *in vitro* study using human hepatocytes, which showed that IL-12 and /or IL-23 at levels of 10 ng/mL did not alter human CYP450 enzyme activities (CYP1A2, 2B6, 2C9, 2D6, or 3A4). However, the clinical relevance of *in vitro* data has not been established. (§7.3). |
| Belatacept (Nulojix) Selective T-cell costimulation blocker 2011 | 7 Drug interactions | |
| | 7.1 Cytochrome P450 Substrates | No formal drug interaction studies have been conducted with Nulojix. Other biologic therapies that are cytokines or cytokine modulators have been shown to affect the expression and/or functional activities of CYP450 enzymes *in vitro* and/or *in vivo*. *In vitro* studies have shown that Nulojix inhibits the production of certain cytokines during an alloimmune response. No studies in kidney transplant patients have been conducted to assess if Nulojix inhibits cytokine production *in vivo*. The potential for Nulojix to alter the systemic concentrations of drugs that are CYP450 substrates has not been studied; however, in the event that kidney transplant patients receiving Nulojix exhibit signs and symptoms of altered administered drugs that are known to be efficacy or adverse events associated with cometabolized by CYP450, the clinician should be aware of potentially altered CYP450 metabolism of these drugs. |
| | 7.2 Use with mycophenolate mofetil | In a pharmacokinetic substudy of Studies 1 and 2, the plasma concentrations of MPA were measured in 41 patients who received fixed MMF doses of 500–1500 mg twice daily with either 5 mg/kg of Nulojix or cyclosporine. The mean dose-normalized MPA $C_{max}$ and $AUC_{0-12}$ were approximately 20% and 40% higher, respectively, with Nulojix coadministration than with cyclosporine coadministration.<br>Clinicians should be aware that there is also a potential change of MPA exposure after crossover from cyclosporine to Nulojix or from Nulojix to cyclosporine in patients concomitantly receiving MMF. |
| Somatropin (rDNA origin) (Genotropin) human growth hormone | Highlights of prescription | *Inhibition of 11 β-hydroxysteroid dehydrogenase type 1*: may require the initiation of glucocorticoid replacement therapy. Patients treated with glucocorticoid replacement |

(*continued*)

**TABLE 10-3** (*Continued*)

| TP Name (Brand Name) Pharmacologic Class Year of Labeling | Item | Labeling Language |
|---|---|---|
| 2011 | information: drug interactions | therapy for previously diagnosed hypoadrenalism may require an increase in their maintenance doses (§7.1; §7.2).<br>*Glucocorticoid replacement*: should be carefully adjusted (§7.2)<br>*Cytochrome P450-metabolized drugs*: monitor carefully if used with somatropin (§7.3)<br>*Oral estrogen*: larger doses of somatropin may be required in women (§7.4)<br>Insulin and/or oral/injectable hypoglycemic agents: may require adjustment (§7.5) |
| | 7 Drug interactions | |
| | 7.1 11 β-hydroxysteroid dehydrogenase type 1 | The microsomal enzyme 11βHSD-1 is required for conversion of cortisone to its active metabolite, cortisol, in hepatic and adipose tissue. GH and somatropin inhibit 11βHSD-1. Consequently, individuals with untreated GH deficiency have relative increases in 11βHSD-1 and serum cortisol. Introduction of somatropin treatment may result in inhibition of 11βHSD-1 and reduced serum cortisol concentrations. As a consequence, previously undiagnosed central (secondary) hypoadrenalism may be unmasked and glucocorticoid replacement may be required in patients treated with somatropin. In addition, patients treated with glucocorticoid replacement for previously diagnosed hypoadrenalism may require an increase in their maintenance or stress doses after initiation of somatropin treatment; this may be especially true for patients treated with cortisone acetate and prednisone because conversion of these drugs to their biologically active metabolites depend on the activity of 11βHSD-1. |
| | 7.3 Cytochrome P450-Metabolized drugs | Limited published data indicate that somatropin treatment increases CYP450-mediated antipyrine clearance in humans. These data suggest that somatropin administration may alter the clearance of compounds known to be metabolized by CYP450 liver enzymes (e.g., corticosteroids, sex steroids, anticonvulsants, cyclosporine). Careful monitoring is advisable when somatropin is administered in combination with other |

| | | |
|---|---|---|
| | | drugs known to be metabolized by CYP450 liver enzymes. However, formal drug interaction studies have not been conducted. |
| | 7.4 Oral estrogen | In patients on oral estrogen replacement, a larger dose of somatropin may be required to achieve the defined treatment goal. (§2.2) |
| | 7.5 Insulin and/or oral/injectable hypoglycemic agents | In patients with diabetes mellitus requiring drug therapy, the dose of insulin and/or oral/injectable agent may require adjustment when somatropin therapy is initiated. (§5.4) |
| 2. Immunosuppressive effect | | |
| Infliximab (Remicade) | 7 Drug Interactions | |
| TNF blocker | 7.3 MTX and other concomitant medications | Specific drug interaction studies, including interactions with MTX, have not been conducted. Concomitant MTX use may decrease the incidence of antiinfliximab antibody production and increase infliximab concentrations. |
| 2011 | | |
| Golimumab (Simponi) | 7 Drug interactions | |
| TNF blocker | | |
| 2011 | 7.1 Methotrexate | For the treatment of RA, Simponi should be used with MTX. (§14.1) Because the presence or absence of concomitant MTX did not appear to influence the efficacy or safety of Simponi in the treatment of PsA or AS, Simponi can be used with or without MTX in their treatment. (§12.3) |
| | 12 Clinical pharmacology | |
| | 12.3 Pharmacokinetics | Patients with RA, PsA, and AS treated with Simponi, 50 mg and MTX had approximately 52%, 36%, and 21% higher mean steady-state trough concentrations of golimumab, respectively, compared with those treated with Simponi 50 mg without MTX. The presence of MTX also decreased antigolimumab antibody incidence from 7% to 2%. (§6.1) For RA, Simponi should be used with MTX. In the PsA and AS trials, the presence or absence of concomitant MTX did not appear to influence clinical efficacy and safety parameters. (§14.1) |
| | | Patients who developed anti-Simponi antibodies generally had lower steady-state serum trough concentrations of Simponi. |

(*continued*)

**TABLE 10-3** (*Continued*)

| TP Name<br>(Brand Name)<br>Pharmacologic Class<br>Year of Labeling | Item | Labeling Language |
|---|---|---|
| Adalimumab<br>(Humira)<br>TNF blocker<br>2012 | 7 Drug interactions<br>7.1 Methotrexate | Humira has been studied in RA patients taking concomitant MTX. Although MTX reduced the apparent adalimumab clearance, the data do not suggest the need for dose adjustment of either Humira or MTX (§12.3) |
| | 12 Clinical pharmacology<br>12.3 Pharmacokinetics | In RA patients receiving 40 mg Humira every other week, adalimumab mean steady-state trough concentrations of approximately 5 μg/mL and 8–9 μg/mL, were observed without and with MTX, respectively. MTX reduced adalimumab apparent clearance after single and multiple dosing by 29% and 44%, respectively, in patients with RA.<br>Adalimumab mean steady-state trough concentrations were slightly higher in psoriatic arthritis patients treated with 40 mg Humira every other week (6–10 μg/mL and 8.5–12 μg/mL, without and with MTX, respectively) compared to the concentrations in RA patients treated with the same dose. |
| Certolizumab pegol<br>(Cimzia)<br>TNF blocker<br>2012 | 6 Adverse reactions<br>Immunogenicity | Antibody formation was associated with lowered drug plasma concentration and reduced efficacy. In patients receiving the recommended Cimzia dosage of 200 mg every other week with concomitant MTX, the ACR20 response was lower among antibody positive patients than among antibody-negative patients (Study RA-I, 48% versus 60%; Study RA-II 35% versus 59%, respectively). In Study RA-III, too few patients developed antibodies to allow for meaningful analysis of ACR20 response by antibody status. In Study RA-IV (monotherapy), the ACR20 response was 33% versus 56%, antibody-positive versus antibody-negative status, respectively. (§12.3) |

| | | |
|---|---|---|
| | 12 Clinical Pharmacology | |
| | 12.3 Pharmacokinetics: drug interaction studies | Methotrexate pharmacokinetics is not altered by concomitant administration with Cimzia in patients with RA. The effect of methotrexate on Cimzia pharmacokinetics was not studied. However, methotrexate-treated patients have lower incidence of antibodies to Cimzia. Thus therapeutic plasma levels are more likely to be sustained when Cimzia is administered with methotrexate in patients with RA. |
| 3. Substrate of the therapeutic enzyme | | |
| Glucarpidase (Voraxaze) Carboxypeptidase 2012 | Highlights of prescription information: drug interactions | Leucovorin is a substrate for Voraxaze. Do not administer leucovorin within 2 h before or after a dose of Voraxaze. (§7.1) Other potential exogenous substrates of Voraxaze include reduced folates and folate antimetabolites. (§7.2) |
| | 7 Drug interactions | |
| | 7.1 Use of Voraxaze with Leucovorin | Leucovorin is a substrate for Voraxaze. Do not administer leucovorin within 2 h before or after a dose of Voraxaze. No dose adjustment is recommended for the continuing leucovorin regimen because the leucovorin dose is based on the patient's pre-Voraxaze methotrexate concentration. (§12.3) |
| | 7.2 Other substrate interference | Other potential exogenous substrates of Voraxaze may include reduced folates and folate antimetabolites. |
| | 12 Clinical pharmacology | |
| | 12.3 Pharmacokinetics: drug interactions | In a study of cancer patients receiving a high-dose methotrexate ($\geq$1 g/m$^2$) and leucovorin rescue regimen, intravenous administration of 50 Units/kg Voraxaze 2 h before leucovorin reduced (6S)-leucovorin $AUC_{0-3h}$ by 33% and $C_{max}$ by 52% and also reduced its active metabolite, (6S)-5-methyltetrahydrofolate, $AUC_{0-3h}$ by 92% and $C_{max}$ by 93%. (§7.1) |
| 4. Mechanisms to be elucidated | | |
| Trastuzumab (Herceptin) HER2/neu receptor antagonist 2010 | 7 Drug interactions | In Study 5, the mean serum trough concentration of trastuzumab was consistently elevated approximately 1.5-fold, when administered in combination with paclitaxel compared to trough concentrations of trastuzumab when administered in combination with an anthracycline and cyclophosphamide. |
| Palifermin | | Heparin may increase systemic exposure (§7) |

(*continued*)

**TABLE 10-3** (*Continued*)

| TP Name (Brand Name) Pharmacologic Class Year of Labeling | Item | Labeling Language |
|---|---|---|
| (Kepivance) Mucocutaneous epithelial human growth factor 2011 | Highlights of prescription information: drug interactions | |
| | 7 Drug interactions | *In vitro* and *in vivo* data showed that palifermin interacts with unfractionated as well as low molecular weight heparins. Heparin coadministration resulted in a fivefold increase in palifermin systemic exposure. Avoid coadministration of palifermin with heparin. If heparin is used to maintain an intravenous line, rinse the line with saline before and after Kepivance administration. (§12.3) |
| | 12 Clinical pharmacology | |
| | 12.3 Pharmacokinetic: drug interactions | The potential PK interaction between palifermin and heparin was evaluated in a single-dose study in 27 healthy subjects receiving palifermin (60 μg/kg) coadministered with and without therapeutic levels of unfractionated heparin. This coadministration resulted in a fivefold increase in palifermin AUC and an 80% decrease in the mean CL. There was no significant effect of palifermin on heparin activity with respect to aPTT. The clinical relevance of this observed increase in palifermin systemic exposure is unclear. (§7) |

[a]Data from Ref. 26.

amount of cytokine and/or cytokine modulator).[20,21,28] However, complex signaling may be involved in TP-DDI and it is not currently possible to ensure that cell culture systems provide the appropriate mix of cell types required for meaningful evaluation *in vitro*. Presently, *in vitro* and animal studies have limited value in the qualitative and quantitative projection of clinical interactions because translation of results from *in vitro* to *in vivo* and from animal to human has been inconsistent, necessitating *in vivo* drug interaction studies. Research that increases our understanding of CYP enzyme or transporter regulation by cytokines may increase the utility of *in vitro* studies. Standardized and optimal assay conditions and the identification of suitable positive controls to monitor assay performance are needed. Until such information is available, it is important to carry out *in vivo* risk-based drug interaction studies for TP-DDI assessments. Many TPs cannot be administered to healthy subjects, and cytokines have a different expression levels between healthy subjects and patients, therefore clinical studies (including TP-DDI studies) are conducted in patients. One efficient study design is the "cocktail" approach. Other *in vivo* study designs allow evaluation of the effect of the TP on substrates for specific CYP enzymes and transporters in targeted patient populations, as described in the next section. Table 10-3 provides an extensive list of labeling examples on PK-based TP-DDI.

Recent BLA review examples include tocilizumab (labeling based on *in vitro* and *in vivo* TP-DDI data information) and rilonacept (labeling without TP-DDI studies).

- If a TP will be used with other drug products (D or TP) as a combination therapy, studies should evaluate the effect of each product on the other. The studies should assess effects on PK and, when appropriate, PD of either drug. This evaluation is particularly important when a drug used in combination has a narrow therapeutic range such as chemotherapeutic agents.

  Examples include cancer therapies in which multiple drugs are combined, such as bevacizumab in combination with intravenous 5-fluorouracil-based chemotherapy including an IV bolus of IFL (irinotecan, 5-FU, and leucovorin) or FOLFOX-4 (oxaliplatin, 5-FU, and leucovorin) for the treatment of first- or second-line metastatic colorectal cancer, and trastuzumab in combination with doxorubicin, cyclophosphamide, and either paclitaxel or docetaxel or in combination with docetaxel and carboplatin for adjuvant treatment of HER2 overexpressing node positive or node negative (estrogen receptor/progesterone receptor [ER/PR] negative or with one high risk feature) breast cancer.[26]

- If there are known mechanisms for interactions or prior experience suggests potential PK or PD interactions, appropriate evaluations for possible interactions should be conducted. Some interactions between drugs and TPs are based on mechanisms other than CYP enzyme or transporter modulation.

  For example, methotrexate, an immunosuppressive agent may alter the clearance of concomitantly administered TPs through the reduction of antibodies formed against TP. Methotrexate decreased the clearance of infliximab

**FIGURE 10-1** Summary of the types of studies that have been used during drug development to evaluate therapeutic protein (TP)–small molecule drug (D) interactions. Evaluation includes the effect of TP on D (TP → D) and the effect of D on TP (D → TP). Broken lines: limited use of *in vitro* studies for informing *in vivo* study design or labeling; CYP: cytochrome P450; PK: pharmacokinetics. (Modified from Ref. 13.)

(a tumor necrosis factor α [TNF-α] blocker), which was associated with the decreased incidence of anti-infliximab antibody formation that affects infliximab clearance. At 8 weeks after a maintenance dose of 3–10 mg/kg of infliximab, median infliximab serum concentrations ranged from approximately 0.5 to 6 μg/mL; however, infliximab concentrations were not detectable (<0.1 μg/mL) in patients who tested positive for antibodies to infliximab.[26,27] The incidence of developing anti-infliximab antibodies was 7% and 21%, respectively, with or without concomitant administration of methotrexate at 12 weeks after last infliximab infusion of a 3 mg/kg dose.[26,27] Methotrexate may also affect the clearance of other TNF-α blocking agents. For example, it decreased the clearance of adalimumab by 29% after single dosing and by 44% after multiple dosing, which may result from reduced immunogenicity incidence; patients treated with concomitant methotrexate had a lower incidence of anti-adalimumab antibody formation than patients on adalimumab monotherapy (1% versus 12%).[26]

Other examples include heparin's effect on palifermin (increased exposure) and paclitaxel's effect on trastuzumab (increased exposure)[26] (Table 10-3), for which mechanisms have not been fully elucidated. In postmarketing studies, coadministration of palifermin with heparin resulted in a 5-fold increase in the systemic exposure of palifermin.[26,29] In clinical studies, administration of paclitaxel in combination with trastuzumab resulted in a 1.5-fold increase in trastuzumab serum levels.[26]

The recently approved glucarpidase label includes information about an interaction between methotrexate and leucovorin involving glucarpidase.[26] Glucarpidase is a carboxypeptidase enzyme indicated for the treatment of toxic plasma methotrexate concentrations ($>1$ μmole/L) in patients with delayed methotrexate clearance due to impaired renal function. In a study of cancer patients receiving a high-dose methotrexate ($\geq 1$ g per $m^2$) and leucovorin rescue regimen, intravenous administration of glucarpidase 2 h before leucovorin reduced (6S)-leucovorin $AUC_{0-3h}$ by 33% and $C_{max}$ by 52%, and also reduced its active metabolite, (6S)-5 methyltetrahydrofolate, $AUC_{0-3h}$ by 92% and $C_{max}$ by 93%.[26] This interaction is anticipated because both methotrexate and leucovorin are substrates of glucarpidase.

In addition to PK interactions, PD interactions can also occur between TP and drug or TP and TP. For example, an increased risk of serious infections has been observed in clinical studies of concurrent therapy for the treatment of rheumatoid arthritis, for eample, etanercept and anakinra, or etanercept and abatacept, without added benefit. Therefore, a warning is stated in the label of a newly approved TNF-α blocker, golimumab, about its risk in combination use with another biologics such as abatacept or anakinra. The labeling states that "use of Simponi (golimumab) with abatacept or anakinra is not recommended" (Table 10-4).[26]

Some PD interactions with TP-DDI have resulted in increased toxicity with combination chemotherapy. It is stated in the Vectibix labeling under Section 10.5 "Warnings and Precautions" that "Vectibix (panitumumab) is not indicated for use in combination with chemotherapy. In an interim analysis of Study 2, the addition of Vectibix to the combination of bevacizumab and chemotherapy resulted in decreased overall survival and increased incidence of NCI-CTC grade 3–5 (87% vs 72%) adverse reactions" (Table 10-4).[26]

As described in Figure 10-1, when there have been known mechanisms or prior experience suggesting potential PK or PD interactions, as illustrated by examples discussed earlier, appropriate *in vitro* and/or *in vivo* assessment for possible interactions have been requested and conducted.

## 10.3 TYPES OF STUDY DESIGNS

*In vitro* methods to evaluate effects of a drug on CYP enzymes and transporters are discussed in detail in other publications and on the FDA Drug Development and Drug Interaction website.[4–8] A white paper from the International Transporter Consortium provides recommendations on *in vitro* models to evaluate transporter-based interactions, including specific decision trees to evaluate the following transporters:

**TABLE 10-4 Examples of Labeling Language for Therapeutic Protein–Drug Interactions (Pharmacodynamics Based)**

| TP Names (Brand Names) Pharmacological Class; Year of Labeling | Item | Labeling Language |
|---|---|---|
| 1. Growth factors (Palifermin and G-CSF) and chemotherapy | | |
| Palifermin (Kepivance) Mucocutaneous Epithelial Human Growth Factor 2011 | Highlights of prescription information: drug interactions | Myelotoxic chemotherapy (§7; §14) |
| | 7. Drug interactions | Do not administer Kepivance within 24 h before, during infusion of, or within 24 h after administration of myelotoxic chemotherapy. (§2.1; §14) In a clinical trial, administration of Kepivance within 24 h of chemotherapy resulted in increased severity and duration of oral mucositis. |
| Filgrastim (Neupogen) Granulocyte colony-stimulating factor (G-CSF) 2012 | Precautions | The safety and efficacy of Neupogen given simultaneously with cytotoxic chemotherapy have not been established. Because of the potential sensitivity of rapidly dividing myeloid cells to cytotoxic chemotherapy, do not use Neupogen in the period 24 h before through 24 h after the administration of cytotoxic chemotherapy (see Dosage and Administration). |
| Pegfilgrastim (Neulasta) G-CSF 2007 | Precautions | Neulasta should not be administered in the period between 14 days before and 24 h after administration of cytotoxic chemotherapy (see Dosage and Administration) because of the potential for an increase in sensitivity of rapidly dividing myeloid cells to cytotoxic chemotherapy |
| 2. Growth factors and myeloablative therapy | | |
| Oprelvekin (Neumega) | Warnings | *Increased toxicity after myeloablative therapy*: Neumega is not indicated after myeloablative chemotherapy. In a randomized, placebo-controlled Phase II study, the |

| | | |
|---|---|---|
| Thrombopoietic growth factor (TGF, IL-11)<br>2009 | | effectiveness of Neumega was not demonstrated (see Clinical Studies, Study in Patients Following Myeloablative Chemotherapy). In this study, a statistically significant increased incidence in edema, conjunctival bleeding, hypotension, and tachycardia was observed in patients receiving Neumega as compared to placebo.<br>The following severe or fatal adverse reactions have been reported in postmarketing use in patients who received Neumega after bone marrow transplantation: fluid retention or overload (e.g., facial edema, pulmonary edema), capillary leak syndrome, pleural and pericardial effusion, papilledema and renal failure. |
| 3. Increased toxicities with concurrent therapy (psychotropic, nephrotoxic, myelotoxic, cardiotoxic or hepatotoxic drugs) | | |
| Aldesleukin (Proleukin)<br>Human recombinant IL-2<br>2011 | Drug interactions | Proleukin may affect central nervous function. Therefore, interactions could occur after concomitant administration of psychotropic drugs (e.g., narcotics, analgesics, antiemetics, sedatives, tranquilizers). Concurrent administration of drugs possessing nephrotoxic (e.g., aminoglycosides, indomethacin), myelotoxic (e.g., cytotoxic chemotherapy), cardiotoxic (e.g., doxorubicin) or hepatotoxic (e.g., methotrexate, asparaginase) effects with Proleukin may increase toxicity in these organ systems. The safety and efficacy of Proleukin in combination with any antineoplastic agents have not been established.<br>In addition, reduced kidney and liver function secondary to Proleukin treatment may delay elimination of concomitant medications and increase the risk of adverse events from those drugs. |
| Peginterferon α-2b (PegIntron)<br>INF-α<br>2011 | 7. Drug interactions<br>7.3 Use with ribavirin (nucleoside analogues) | Hepatic decompensation (some fatal) has occurred in cirrhotic HIV/HCV co-infected patients receiving combination antiretroviral therapy for HIV and INF-α and ribavirin. Adding treatment with INF-α alone or in combination with ribavirin may increase the risk in this patient subset. Patients receiving interferon with ribavirin and NRTIs should be closely monitored for treatment-associated toxicities, especially hepatic decompensation and anemia. Discontinuation of NRTIs should be considered as medically appropriate (see Individual NRTI Product Information). Dose reduction or discontinuation of interferon, ribavirin, or both should also be considered if worsening |

|---|---|---|
| | | clinical toxicities are observed, including hepatic decompensation (e.g., Child-Pugh $< 6$). |
| 4. Increased infections with concurrent therapy | | |
| Etanercept (Enbrel) TNF blocker 2009 | Precaution: drug interactions | In a study in which patients with active RA were treated for $\leq 24$ weeks with concurrent Enbrel and anakinra therapy, a 7% rate of serious infections was observed, which was higher than that observed with Enbrel alone (0%). Two percent of patients treated concurrently with Enbrel and anakinra developed neutropenia (ANC $< 1 \times 10^9$/L |
| | | In a study of patients with Wegener's granulomatosis, the addition of Enbrel to standard therapy (including cyclophosphamide) was associated with a higher incidence of noncutaneous solid malignancies. The use of Enbrel in patients receiving concurrent cyclophosphamide therapy is not recommended (see Warnings: Malignancies and Adverse reactions: Malignancies). |
| | | Patients in a clinical study who were on established therapy with sulfasalazine, to which Enbrel was added, were noted to develop a mild decrease in mean neutrophil counts compared to groups treated with either Enbrel or sulfasalazine alone. The clinical significance of this observation is unknown. |
| Infliximab (Remicade) TNF blocker 2011 | Highlights of prescription information: drug interactions | Use with anakinra or abatacept increased risk of serious infections (§7.1) |
| | 7 Drug interactions | |
| | 7.1 Use with anakinra or abatacept | An increased risk of serious infections was seen in clinical studies of other TNF-α-blocking agents used in combination with anakinra or abatacept, with no added clinical benefit. Because of the nature of the adverse reactions seen with these |

| | | |
|---|---|---|
| | | combinations with TNF-blocker therapy, similar toxicities may also result from the combination of anakinra or abatacept with other TNF-α-blocking agents. Therefore, the combination of Remicade and anakinra or abatacept is not recommended. (§5.9; §5.10) |
| | 7.2 Use with tocilizumab | The use of tocilizumab in combination with biological DMARDs, such as TNF antagonists, including Remicade, should be avoided because of the possibility of increased immunosuppression and increased risk of infection. |
| Adalimumab (Humira) TNF blocker 2012 | Highlights of prescription information: drug interactions | Abatacept increased risk of serious infection (§5.1; §5.11; §7.2)<br>Anakinra increased risk of serious infections (§5.1; §5.7; §7.2) |
| | 7 Drug interactions | |
| | 7.2 Biologic products | In clinical studies in patients with RA, an increased risk of serious infections has been seen with the combination of TNF blockers with anakinra or abatacept, with no added benefit; therefore, use of Humira with abatacept or anakinra is not recommended in patients with RA. (§5.7; 5.11) A higher rate of serious infections has also been observed in patients with RA treated with rituximab who received subsequent treatment with a TNF blocker. There is insufficient information to provide recommendations regarding the concomitant use of Humira and other biologic products for the treatment of RA, PsA, AS, Crohn's disease, and plaque psoriasis. |
| Golimumab (Simponi) TNF blocker 2010 | Highlights of prescription information: drug interactions | Abatacept increased risk of serious infection (§5.1; §5.5; §7.2)<br>Anakinra increased risk of serious infections (§5.1; §5.6; §7.2) |
| | 7 Drug interactions | |
| | 7.2 Biologic products for RA, PsA, and/or AS | An increased risk of serious infections has been seen in clinical RA studies of other TNF blockers used in combination with anakinra or abatacept, with no added benefit; therefore, use of Simponi with abatacept or anakinra is not recommended. (§5.6) A higher rate of serious infections has also been observed in RA patients treated with rituximab who received subsequent treatment with a TNF blocker. There is insufficient |

| | | information to provide recommendations regarding the concomitant use of Simponi and other biologic products approved to treat RA, PsA, or AS. |
| Certolizumab pegol (Cimzia) TNF blocker 2012 | Highlights of prescription information: drug interactions | Use with biological DMARDs increased risk of serious infections (§5.8; §7.1) |
| | 7 Drug interactions | |
| | 7.1 Use with anakinra, abatacept, rituximab, and natalizumab | An increased risk of serious infections has been seen in clinical studies of other TNF-blocking agents used in combination with anakinra or abatacept, with no added benefit. Formal drug interaction studies have not been performed with rituximab or natalizumab. Because of the nature of the adverse events seen with these combinations with TNF-blocker therapy, similar toxicities may also result from the use of Cimzia in these combinations. There is not enough information to assess the safety and efficacy of such combination therapy. Therefore, the use of Cimzia in combination with anakinra, abatacept, rituximab, or natalizumab is not recommended. (§5.8) |
| Canakinumab (Ilaris) IL-1β blocker 2009 | 7 Drug interactions | |
| | 7.1 TNF and IL-1 blockers | An increased incidence of serious infections and an increased risk of neutropenia have been associated with administration of another IL-1 blocker in combination with TNF inhibitors in another patient population. Use of Ilaris with TNF inhibitors may also result in similar toxicities and is not recommended because this may increase the risk of serious infections. (§5.1) |
| | | The concomitant administration of Ilaris with other drugs that block IL-1 has not been studied. Based on the potential for pharmacological interactions between Ilaris and a recombinant IL-1ra, concomitant administration of Ilaris and other agents that block IL-1 or its receptors is not recommended |

| | | |
|---|---|---|

P-glycoprotein (P-gp), breast cancer resistance protein (BCRP), organic anion transporting polypeptide (OATP), organic anion transporter (OAT), and organic cation transporter (OCT). These models, when used with other *in vitro* and *in vivo* human data, can inform clinical study design and provide helpful information on drug labels.[30–32] However, at the present time, there are no well–validated *in vitro* models that can help predict TP-DDI. This knowledge gap was acknowledged at a AAPS/NBC TP-DDI workshop held in 2010.[12] Additional research is ongoing to further explore the utility of *in vitro* models for TP-DDI assessments.

An important consideration for most TP-DDI studies is the general need to conduct these studies in patient populations instead of healthy subjects. There are often concerns with the toxicity of the TP or drug in healthy subjects, and PK characteristics and/or target protein expression levels may differ between patients and healthy subjects. The need to conduct studies in patient populations has an impact on the feasibility of study designs.

Table 10-5 lists study designs that have been used in the *in vivo* evaluation of drug interactions involving TP products in human subjects. In studies with crossover designs, each subject serves as his or her own control, minimizing variability and allowing smaller sample size with increased statistical power. Many TP-DDI studies have been conducted using a one-way crossover

**TABLE 10-5 Examples of Study Designs Used to Assess Therapeutic Protein and Small Molecule Drug Interactions[a]**

| Study Designs[b] | Therapeutic Protein (TP) and Drug (D) Names | Study Purposes[c] |
|---|---|---|

[a]Data from Refs. 13,14,26,33–38.
[b]Study design: the administration of D or TP was listed sequentially; for example, "D; TP; TP + D" indicates that D alone was given followed by TP alone, which was followed by TP and D given together; "D; D + TP (×4)" indicates that D alone was given followed by D and TP given together for 4 cycles (days or weeks).
[c]Study purpose: TP → D denotes a study in which the effect of TP on D is examined; D → TP denotes a study in which the effect of D on TP is examined.
[d]Comparison of D exposure was made between Groups A (first D) and Group B (TP + D).
[e]This portion of study is a one-way crossover (sequential) design.
5-FU:5-Fluorouracil; IL-6: Interlukin-6; INF-α: Interferon-α; TNF-α: Tumor Necrosis Factor-α.

(sequential) design. This study design is often used for evaluation of the effect of TP on concomitant chemotherapy agents (TP → D) in the oncology clinical setting. In the evaluation of TP-DDI between bevacizumab and carboplatin, patients received carboplatin first and bevacizumab was then added to the regimen. PK information collected in both occasions was evaluated to determine the effect of bevacizumab on carboplatin (Table 10-5). This within-study crossover design may not be feasible, however, for the assessment of the effect of chemotherapy agents on TP (D → TP). Many TP products, such as mAbs, have long half-lives, nonlinear PK because of a component of saturable target-mediated clearance, and potential for formation of antiproduct antibodies (APAs) that may alter their own clearance. These unique characteristics of TP produce unavoidable sequence effects, which preclude the use of crossover designs for the assessment of the effect of chemotherapy agents on TP in the combination

therapy (D → TP). Alternative study designs, such as parallel group study or population PK analysis, have therefore been used for such assessments.

Population PK studies have been conducted to evaluate drug interactions, and sponsors have been encouraged to include population PK sample collection (and PD, if appropriate) and data analysis in late phase clinical trials to evaluate patient factors and concomitant medications that may contribute to the variability in systemic exposure and/or drug response for small molecular drugs.[2,4–8] Population PK analyses have also been used to determine the effect of concomitant medications on PK and PD of TPs. Table 10-5 includes examples of the use of a population PK approach for evaluating the effect of a drug on a TP (D → TP). For example, the tocilizumab label states that population PK analyses did not detect any effect of methotrexate, nonsteroidal anti-inflammatory drugs, or corticosteroids on tocilizumab clearance.[26] In most cases, the concentrations of concomitantly administered drugs are not determined in these clinical trials, and therefore the studies do not provide information on the effect of a TP on the exposure of concomitantly used drugs (TP → D).

Table 10-5 also shows examples of parallel study design used in the assessment of the TP → D or D → TP effects. In addition to parallel design studies, some assessments were made using a cross-study evaluation, which may involve comparisons of data between healthy subjects and patients or comparisons of data between combination therapy and monotherapy. Data from such analyses should be considered as "hypothesis-generating" and the results generally need to be confirmed.

Finally, Table 10-5 presents information collected in association studies, such as the evaluation of correlation between cytokine levels and enzyme activities. Association studies provide mechanistic understanding of the effects of cytokines on CYP enzyme or transporter activities and predict effects of various cytokine modulators on the activities of specific CYP enzymes or transporters.

## 10.4 LABELING IMPLICATIONS

When a drug product's optimal dose for an indication has been selected based on assessment of the overall relation of risk-to-benefit, it is relatively straightforward to determine dosing adjustments needed for patients with specific intrinsic and extrinsic factors that alter their PK profiles: dosing adjustments for individuals with altered PK profiles are generally made to achieve the same systemic exposure as has been shown to be safe and effective for patients without altered PK profiles.[4–8,12] The principles that guide recommendations for drug dosing adjustments have been used in the interpretation of the results from TP-DDI studies. Details of the drug interaction results have been included in the pharmacokinetics subsection (12.3) of the clinical pharmacology section of the labeling.[2,39]

Tables 10-3 and 10-4 provide examples of TP-DDI information (PK and PD based, respectively) in current product labels. Although some TP-DDI information is included in TP labels, unlike small molecule drugs, where some drug interactions have resulted in specific labeling language in the sections titled "Highlights,"

"Contraindications," and "Dosage and Administration," most TP labels include descriptive information about drug interactions in the sections called "Drug interactions," "Clinical Pharmacology," and "Warnings and Precautions," suggesting lesser perceived clinical significance of these interactions with TPs. In particular, the current labels do not recommended specific dosing adjustments for TP-DDI in the "Dosage and Administration" section.

The label for tocilizumab, an interleukin 6 (IL-6) receptor inhibitor approved in the United States for rheumatoid arthritis and systemic juvenile idiopathic arthritis, includes results of studies that demonstrate an effect of tocilizumab on the PK of CYP2C19 or CYP3A substrates.[24–26] CYP enzymes in the liver are downregulated by infection and inflammation stimuli, including cytokines such as IL-6. Inhibition of IL-6 signaling in rheumatoid arthritis patients treated with tocilizumab may restore CYP enzyme activities to higher levels than those not treated with tocilizumab leading to increased metabolism of drugs that are CYP enzyme substrates. The tocilizumab labeling states that the effect of tocilizumab on CYP enzymes may be clinically relevant for CYP450 substrates with a narrow therapeutic index, where the dose is individually adjusted. It further recommends that

> Upon initiation or discontinuation of tocilizumab, in patients being treated with these types of medicinal products, therapeutic monitoring of effect (e.g., warfarin) or drug concentration (e.g., cyclosporine or theophylline) should be performed and the individual dose of the medicinal product adjusted as needed.[26]

The development of physiologically based PK (PBPK) models linking the *in vitro* CYP suppression data for tocilizumab to the *in vivo* CYP alternation (measured via changes in systemic exposure of probe substrates, such as simvastatin) helps explain the association between IL-6 levels and CYP suppression.[40] PBPK models have been shown to be a useful tool in clinical pharmacology evaluations, including drug–drug interactions involving small molecule drugs.[41,42]

Several TP labels included language regarding the potential for drug interactions (either at the time of market approval or at their labeling updates). These examples include rilonacept (IL-1β blocker), golimumab (TNF-α blocker), balatacept (IL-2 modulator), infliximab (TNF-α blocker), and ustekinumab (anti-IL12/IL23 mAb) (Table 10-3). Labeling language for these cytokine modulators indicates that increased levels of cytokines (such as IL-1, IL-6, IL-10, TNF-α, IFN-α) during inflammation can alter the expression or activity of CYP enzymes, and that these cytokine modulators may normalize the activity of CYP enzymes, thus affecting systemic exposure of CYP enzyme substrates. The labels include a general recommendation to monitor the effect on drug concentration and to adjust the dose as needed for CYP enzyme substrates with a narrow therapeutic index (such as warfarin, cyclosporine, theophylline). However, no specific TP-DDI study results have been included in the labels of these TPs. In some cases, postmarketing drug interaction studies that provide useful information are added to the labels at a later date.[29]

## 10.5 CONCLUSION

Information about drug–drug interactions is critical to public health. The use of therapeutic proteins has increased in recent years, and they are often used in combination with small molecule drugs in critical therapeutic areas. It is anticipated that as more data are collected and the understanding of potential therapeutic protein–drug interactions increases, we will be better able to assess the potential for TP-DDIs during the development of therapeutic proteins.

# DISEASE–DRUG–DRUG INTERACTION ASSESSMENTS FOR TOCILIZUMAB—A MONOCLONAL ANTIBODY AGAINST INTERLEUKIN-6 RECEPTOR TO TREAT PATIENTS WITH RHEUMATOID ARTHRITIS

XIAOPING ZHANG and BARBARA J. BRENNAN

## 11.1 INTRODUCTION

Tocilizumab (TCZ, Actemra) is a recombinant humanized monoclonal antibody of the immunoglobulin G (IgG) subclass that selectively binds to human interleukin 6 (IL-6) receptors. TCZ binds to both membrane-bound and soluble forms of IL-6R, blocking signal transduction pathways through competitive inhibition of IL-6 binding.[1] TCZ 8 mg/kg given intravenously (IV) is currently approved for the treatment of rheumatoid arthritis (RA) in over 106 countries, including the United States,[2] Canada,[3] Australia,[4] European countries,[5] and Japan.[6] IL-6 receptor blockade was considered as a mechanism for pharmacologic treatment of RA due to the central role of IL-6 in inflammatory processes. IL-6 is a pleiotropic cytokine with numerous activities, including effects on the immune response and inflammation (e.g., interaction with neutrophils in the synovium), bone metabolism, and hematopoiesis.[7,8] Elevated IL-6 levels have been found in the serum and synovial fluid of RA patients, and inflammatory cell infiltration has been correlated with IL-6 levels in synovial tissues.[9] Furthermore, IL-6 levels correlate with disease activity in RA patients and improvement of the disease after treatment with disease-modifying antirheumatic drugs (DMARDs) is accompanied by a reduction in serum IL-6.[10]

A systematic review of TCZ for RA has been reported.[11] Ten published clinical trials (seven Phase III, three Phase II) for TCZ were retrieved. Compared with methotrexate (MTX) monotherapy, TCZ 8 mg/kg IV monotherapy had higher ACR20 ($p < 0.001$), ACR50 ($p < 0.002$), and ACR70 ($p < 0.001$) response rates at week 24. TCZ 8 mg/kg IV plus oral MTX had a higher ACR20 response rate than oral MTX plus placebo in patients with RA who failed to respond to MTX or anti–tumor necrosis factor therapy ($p < 0.001$). Patients receiving TCZ 8 mg/kg had less radiographic progression as assessed by Genant-modified Sharp score (85% had no progression progression) than the control group (67% had no progression) ($p < 0.001$). In the all exposure population composed of 4009 RA patients (3577 received treatment for at least 6 months, 3309 for at least one year; 2954 received treatment for at least 2 years and 2189 for 3 years), the rate of serious infections was 4.7 events/100 patient-years of exposure in all TCZ exposure groups containing 4009 patients (3577 received TCZ for at least 6 months, 3309 for at least one year, 2595 for at least 2 years and 2189 for 3 years).[2] A greater frequency of neutropenia, thrombocytopenia, hyperlipidemia, and transaminitis was observed with TCZ compared with placebo.

Following 4 and 8 mg/kg administration of TCZ to RA patients, serum TCZ concentration-time profiles were adequately described by a 2-compartment disposition pharmacokinetic model with parallel linear and nonlinear elimination kinetics. At low TCZ concentrations, the target-mediated elimination (e.g., via IL-6R) is the predominant elimination pathway. As the concentration of TCZ increases, the target is gradually saturated, and linear clearance by the nonspecific reticuloendothelial system becomes a predominant elimination pathway. Total TCZ clearance is therefore increased with time as TCZ concentration decreases after administration. As a result, the terminal half-life of TCZ increases as TCZ concentration decreases during a dosing interval. The half-life of TCZ was up to 11 to 13 days for therapeutic dose of 4 and 8 mg/kg, respectively, every 4 weeks at steady state.[12]

Several biomarkers of TCZ activity have been routinely measured in clinical pharmacology studies as well as in Phase III studies of TCZ, including IL-6 plasma levels, soluble IL-6 receptor plasma levels, and C-reactive protein (CRP). In RA patients, mean plasma IL-6 concentrations increase significantly after TCZ IV infusion and remain elevated for at least 4 weeks after a single 10 mg/kg dose and return to baseline after approximately 8 weeks.[13] This increase in IL-6 is thought to occur as a result of IL-6R blockade inhibiting clearance of IL-6 from the serum.[14,15] Similarly, increases in the soluble IL-6 receptor are also observed after administration of TCZ. CRP is an acute phase protein that is elevated in the serum of RA patients and used as a marker of inflammation. As a result of IL-6R blockade by TCZ, CRP serum levels are reduced to within the normal range by approximately 7 days postinfusion.[13]

The role of proinflammatory cytokines, such as interleukins, interferons, and tumor necrosis factor α (TNF-α), in regulation of cytochrome P450 (CYP) mediated drug metabolism has been well described.[16–18] There are several examples of altered drug metabolism in patients with acute or chronic inflammatory conditions, such as influenza and cancer. Furthermore, several reports have described the ability

of interferon to reduce the metabolic activity of several CYP enzymes in clinical drug–drug interactions studies.[19–21]

IL-6 has been reported to down-regulate several CYP isoforms *in vitro*, with CYP3A4 being the most sensitive.[22–24] RA patients have elevated mean IL-6 levels (~50–60 pg/mL) as compared to approximately 5 pg/mL or less in healthy subjects.[25] Treatment with TCZ blocks the IL-6 signaling pathway and therefore has the potential to reverse the downregulation of the CYP system and restore metabolic activity. In this situation, a decrease from pretreatment baseline concentrations would be expected for drugs that are substrates of CYP upon initiation of treatment with TCZ.

## 11.2 PRECLINICAL EVALUATION

As a first step to investigate the potential for disease–drug–drug interactions (DDDIs) resulting from reduced IL-6 signaling, an *in vitro* assessment in human hepatocytes was performed.[26] The effects of TCZ and IL-6 on hepatic drug metabolizing enzyme expression levels were investigated. The hepatocytes were obtained as cells seeded on 24 well plates. Expression levels of mRNA for CYP3A4, 2D6, 1A2, 2B6, 2C19, and 2C9 were evaluated in the presence and absence of IL-6 at a low concentration of 0.5 ng/mL and at a high concentration of 12.5 ng/mL. Expression levels were also assessed in the presence of 12.5 ng/mL IL-6 plus 250 μg/mL of TCZ. All incubations lasted 72 h.

Results of the hepatocyte experiment are provided in Table 11-1. IL-6 had a profound impact on CYP3A4 expression, particularly at the high concentration of 12.5 ng/mL. No changes were apparent in the other isoforms at the low IL-6 concentration of 0.5 ng/mL; however, there was suppression of all isoforms at the high concentration of 12.5 ng/mL. The addition of TCZ at a concentration of 250 μg/mL to the incubation was able to completely prevent the IL-6-mediated downregulation of CYP3A4. A similar effect was apparent for the other CYP isoforms to a lesser extent than for CYP3A4. These *in vitro* findings supported that a clinical

disease–drug–drug interaction between TCZ and drugs that are metabolized via CYP enzymes should be evaluated in RA patients to assess the clinical relevance of the *in vitro* findings.

## 11.3 CLINICAL DDDI EVALUATIONS

Following the *in vitro* assessment, three clinical DDDI assessments were performed in patients with RA. Because the mechanism underlying the potential clinical DDDI is a function of the increased IL-6 levels in RA patients, it was essential that the clinical studies were performed in RA patients as opposed to healthy subjects. The effect of TCZ on the pharmacokinetics (PK) exposure of omeprazole (a sensitive CYP2C19 substrate with some CYP3A4 involvement),[26] dextromethorphan (a sensitive CYP2D6 substrate with some CYP3A4 involvement),[26] and simvastatin (a sensitive CYP3A4 substrate),[27] was therefore studied in RA patients. In addition to the studies that were planned with a reasonable mechanistic hypothesis, supported by *in vitro* data suggesting a clinical DDDI could be likely, the effect of TCZ on methotrexate (MTX) PK was also evaluated clinically because MTX is a commonly administered concomitant medication for the treatment of RA.[29] IL-6 has been reported *in vitro* to suppress mRNA of some anion transporters such as MRP2 that are involved in MTX elimination.[28] Elevated IL-6 levels present in RA patients could therefore be associated with downregulation of these transporters. If true, TCZ may reverse this IL-6-induced downregulation of transporters as it does for CYP3A4. Therefore DDDI for TCZ and MTX in RA patients was also evaluated.[29] The potential for other common concomitant medications in RA patients to alter the PK of TCZ was evaluated by population PK analysis.[12]

The first clinical DDDI study was a two-part study that evaluated the effect of TCZ on the PK of omeprazole (OME) and dextromethorphan (DEX) in 18 and 13 patients with RA, respectively. Patients diagnosed with RA based on the 1987 American College of Rheumatology (ACR) criteria[30] with CRP $> 1.5$ mg/dL, were enrolled. DMARDs or nonsteroidal anti-inflammatory drugs (NSAIDs) had been stabilized for at least 2 weeks before receiving the study drug on day 1. More criteria for inclusion and exclusion from the study can be found elsewhere.[26] All patients who participated in the OME evaluation were genotyped for CYP2C19 metabolizer status.

The second clinical DDDI study was a two-part study evaluated the effect of TCZ on the PK of simvastatin (SIM) in 12 patients in Group 1 and effect of TCZ on the PK of methotrexate (MTX) in 12 patients in Group 2. Patients diagnosed with RA based on the 1987 ACR criteria[30] with CRP $> 1.5$ mg/dL, were enrolled. MTX was given for at least 12 weeks immediately before day 1, of which the last 8 weeks were at a stable dose between 10 and 25 mg/week. Patients on other DMARDs were excluded. NSAIDs and oral corticosteroids (CSs) were stabilized for at least 2 weeks before receiving the study drug on day 1. More criteria for inclusion and exclusion from the study can be found elsewhere.[27]

### 11.3.1 Omeprazole DDDI Evaluation

The OME DDDI study was an open-label, two period, single-dose crossover study in 18 patients with RA.[13,26] Of the 18 patients, 5 were classified as CYP2C19 poor metabolizers (PMs), 8 were extensive metabolizers (EMs), and 5 were considered intermediate metabolizers (IMs). All patients received a single dose of OME 10 mg orally on day 1, followed by a single 1-h IV infusion of 8 mg/kg of TCZ on day 8 and then another single oral 10 mg dose of OME 7 days after the TCZ infusion. Seven days was selected as the appropriate time period necessary to evaluate changes in CYP-mediated metabolism as a result of inhibition of IL-6 signal transduction. Serial blood samples were collected after each OME dose for measurement of plasma OME concentrations.

The mean (%CV) OME PK parameters in the absence and presence of TCZ are provided in Table 11-2 for each of the CYP2C19-metabolizer groups.

As expected, plasma exposure of OME at baseline was lower in the EM group as compared to the IM or PM groups. One week after administration of TCZ, plasma OME concentrations were lower than those measured at baseline. The geometric mean ratio of $AUC_{0-\infty}$ and $C_{max}$ and associated 90% confidence intervals for each group are provided in Table 11-2. The decrease was more pronounced in the EM group as compared to the IM or PM group, as expected, because patients with the EM phenotype should be more sensitive to an inflammation-associated reduction in CYP2C19 activity. In the EM group, OME $AUC_{0-\infty}$ was reduced by approximately 28% as compared to an approximate 12% decrease in both the IM and PM groups.

### 11.3.2 Dextromethorphan DDDI Evaluation

The DDDI study with DEX was an open-label, single-dose cross-over study conducted in RA patients. Thirteen RA patients received a single 30-mg dose of DEX alone and a single 30-mg dose of DEX 1 week after receiving a single 1-h IV infusion of TCZ 8 mg/kg. Blood samples were collected for evaluation of DEX plasma exposure. DEX is metabolized primarily by CYP2D6 to dextrorphan, which then undergoes further metabolism via CYP3A4. Therefore, both DEX and dextrorphan plasma concentrations were measured to assess effects on both CYP2D6 and CYP3A4.

After administration of TCZ, plasma exposure to DEX was essentially unchanged, as shown in Table 11-3, with $AUC_{0-\infty}$ geometric mean ratio of approximately 1 and associated 90% confidence intervals for $AUC_{0-\infty}$ between the equivalence limits of 80% and 125%. However, exposure to the major metabolite, dextrorphan, a CYP3A4 substrate, was approximately 30% lower in the presence of TCZ, suggesting a potential effect of TCZ on CYP3A4 activity. Although this study provided some insight into the potential for alteration of CYP3A4-mediated metabolism by TCZ, DEX is not considered a sensitive CYP3A4 substrate. Therefore a subsequent DDDI study was planned with simvastatin to fully characterize the effect of TCZ on CYP3A4 activity in RA patients.

### 11.3.3 Simvastatin DDDI Evaluation

To further elucidate and characterize the effect of IL-6 blockade with TCZ on the metabolic activity of CYP3A4, a second DDDI study was undertaken to examine the impact of TCZ on the pharmacokinetics of SIM, which is considered a sensitive substrate of CYP3A4. SIM is almost exclusively metabolized by CYP3A4 and is recommended as a sensitive probe substrate by the FDA.[31] This study was performed in 12 RA patients and he study design is illustrated in Figure 11-1.

**FIGURE 11-1** Design of simvastatin disease–drug–drug interaction study. PK: pharmacokinetics; TCZ: tocilizumab. PO: per oral. IV: intravenous.

Briefly, a single 40 mg dose of SIM was administered alone, followed by a single 10 mg/kg infusion of TCZ after a 7-day washout period (day 8). In this study a 10-mg/kg dose of TCZ was used to represent steady-state exposure of the 8 mg/kg every 4 weeks regimen. One week (day 15) after the TCZ infusion, another single 40-mg dose of SIM was administered to evaluate the peak effect of TCZ on CYP3A4 activity. In this study, the time course of the potential effect on CYP3A4 activity was also evaluated by administration of an additional 40-mg dose of SIM 5 weeks after the TCZ infusion (day 43), to determine if the effect on CYP3A persisted. Blood samples were collected serially for pharmacokinetic assessment of SIM and its major metabolite, simvastatin acid, which is also a CYP3A4 substrate.

The study included male and female RA patients aged 18 to 75 years. Inclusion and exclusion criteria for the study were similar to the previous drug–drug interaction study.[26,27]

Mean $AUC_{0\text{–last}}$ and $C_{max}$ for SIM and simvastatin acid are provided in Table 11-4. The SIM $AUC_{0\text{–last}}$ in RA patients in this study was 102 ng·h/mL compared to values ranging from 11 to 25 ng·h/mL in studies in healthy subjects reported in the literature.[32–35] One week after administration of TCZ the $AUC_{0\text{–last}}$ and $C_{max}$ of SIM were significantly reduced by approximately 57%. This effect persisted even 5 weeks after the TCZ infusion, with an approximate reduction from baseline in $AUC_{0\text{–last}}$ of 40%. The findings were similar for simvastatin acid. Plasma concentrations were higher in RA patients at baseline as compared to literature reports in healthy adults ($AUC_{0\text{–last}}$ of 35 ng·h/mL in RA patients vs. 18 to 26 ng·h/mL in healthy adults). The $AUC_{0\text{–last}}$ of simvastatin acid was reduced by approximately 40% and 20%, 1 week and 5 weeks after TCZ administration, respectively. The effect of TCZ on CYP3A4 activity 5 weeks post dosing was less than 1 week post dosing because SIM $AUC_{0\text{–last}}$ and $C_{max}$ were higher on day 43 than on day 15 (Table 11-4).

These findings are consistent with the pattern of IL-6 receptor blockade by TCZ as evidenced by the time course of CRP (Figure 11-2). The maximum effect of TCZ in normalizing CRP levels was observed 1 week after infusion and corresponded to the maximum decrease in SIM levels. At 5 weeks after the infusion, serum concentrations of CRP represented only one-third of the baseline level, and the effect on SIM exposure was less pronounced.

### 11.3.4 Methotrexate DDDI Evaluation

The effect of TCZ on MTX PK was evaluated as a second part of the SIM DDDI study. Patients receiving MTX 10–25 mg/week as part of their RA therapy were enrolled in the study. All patients had serial PK samples collected for MTX, 1 week before TCZ administration and then again after the TCZ infusion, at similar times as for SIM. Results of the clinical DDDI evaluation confirmed that no significant changes were observed in MTX exposure in the presence of TCZ with geometric mean ratio of $C_{max}$ and $AUC_{0'\text{last}}$ for MTX with and without TCZ coadministration of 1.0 (0.92–1.09) and 1.10 (1.03–1.18), respectively.[29] Despite that IL-6 has been reported *in vitro* to suppress mRNA to downregulate the levels of MRP2,[28] which

**TABLE 11-4 Mean Simvastatin (SIM) and Simvastatin Acid Pharmacokinetics Parameters and Ratio of Geometric Least Squares Mean**

| | Simvastatin | | | Simvastatin Acid | | |
|---|---|---|---|---|---|---|
| | SIM Day 1 | SIM + TCZ Day 15 | SIM + TCZ Day 43 | SIM Day 1 | SIM + TCZ Day 15 | SIM + TCZ Day 43 |
| $AUC_{0-last}$ (ng·h/mL) | 102 (43) | 42.9 (41) | 63.2 (54) | 35.1 (72) | 22.4 (75) | 28 (63) |

| $C_{max}$ ratio | – | 0.43 [0.33–0.55] | 0.61 [0.47–0.78] | – | 0.59 [0.47–0.74] | 0.7 [0.56–0.88] |

[a]Coefficient of variation ([standard deviation/mean]100%) is in parentheses; 90% confidence interval is in brackets.
$AUC_{0-last}$: area under plasma concentration-time curve from zero to the last measurable concentration; $C_{max}$: maximum plasma concentration; TCZ: tocilizumab.

**FIGURE 11-2** Mean (±SE) C-reactive protein concentration vs. time.

is one of the main efflux transporters involved in the MTX elimination,[36] the absence of DDDI may suggest that elevated levels of IL-6, which as present in RA patients, have no effect on the expression and/or activity of MRP2 *in vivo* (expression of MRP2 was not measured in this study). Alternatively, other transporters might have compensated for MRP2 action.

### 11.3.5 Additional Drug–Drug Interaction Evaluations

The potential for drug–drug interactions with common agents coadministered for the treatment of RA was evaluated using population PK analysis with concentration-time data collected from RA patients enrolled in four Phase III clinical trials.[12] In this analysis, the concomitant use of RA-specific treatments–including MTX, chloroquine and derivatives, azathioprine, leflunomide, glucocorticoids, folic acid and derivatives, nonsteroidal anti-inflammatory agents, cyclooxygenase inhibitors, and analgesics (paracetamol, tramadol, codeine, and derivatives)—did not alter the PK of TCZ.

## 11.4 LABELING

The findings of these clinical DDDI evaluations have been incorporated into TCZ prescribing information globally to provide important guidance to clinicians caring for RA patients and managing comorbidities that require additional medications. As an example, we provide an excerpt from the US prescribing information:[2]

Interactions with CYP450 Substrates

Cytochrome P450s in the liver are down-regulated by infection and inflammation stimuli including cytokines such as IL-6. Inhibition of IL-6 signaling in RA patients treated with tocilizumab may restore CYP450 activities to higher levels than those in the absence of tocilizumab leading to increased metabolism of drugs that are CYP450 substrates. In vitro studies showed that tocilizumab has the potential to affect expression of multiple CYP enzymes including CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6 and CYP3A4. Its effects on CYP2C8 or transporters is unknown. In vivo studies with omeprazole, metabolized by CYP2C19 and CYP3A4, and simvastatin, metabolized by CYP3A4, showed up to a 28% and 57% decrease in exposure one week following a single dose of ACTEMRA, respectively. The effect of tocilizumab on CYP enzymes may be clinically relevant for CYP450 substrates with narrow therapeutic index, where the dose is individually adjusted. Upon initiation or discontinuation of ACTEMRA, in patients being treated with these types of medicinal products, therapeutic monitoring of effect (e.g., warfarin) or drug concentration (e.g., cyclosporine or theophylline) should be performed and the individual dose of the medicinal product adjusted as needed. Prescribers should exercise caution when ACTEMRA is coadministered with CYP3A4 substrate drugs where decrease in effectiveness is undesirable, e.g., oral contraceptives, lovastatin, atorvastatin, etc. The effect of tocilizumab on CYP450 enzyme activity may persist for several weeks after stopping therapy.

## 11.5 DISCUSSION

The results of the clinical DDDI evaluations performed with TCZ confirm the longstanding hypothesis that clinically relevant drug interactions can occur as a result of reversal of an inflammatory process that suppresses CYP metabolic enzyme activity, hence "normalizing" activity. However, unlike direct drug–drug interactions, disease–drug–drug interactions are relevant only for CYP substrates with a narrow therapeutic index for which doses are individually adjusted. For those drugs, monitoring of drug effects or concentrations should be performed within 2 weeks upon initiation of TCZ therapy or several weeks after stopping the therapy. From these evaluations, CYP3A4 appears to be the most sensitive isozyme, based on *in vitro* and *in vivo* findings.

When considering the DDDI observed with simvastatin, $AUC_{0-\infty}$ was approximately sixfold higher in RA patients at baseline compared to healthy subjects (105 vs. 17.3 ng·h/mL). This observation confirmed that CYP3A4 activity is suppressed in RA patients by RA-associated inflammation. Upon initiation of TCZ (1 week postinfusion), SIM $AUC_{0-\infty}$ was reduced by approximately twofold (105 vs. 44.9 ng·h/mL), indicating that suppressive effect of inflammation on CYP3A4 was reversed and CYP3A4 activity was increased approaching "normalization." After stopping TCZ treatment (5 weeks postinfusion), SIM $AUC_{0-\infty}$ increased compared to the exposure at week 1 (65.2 vs 44.9 ng·h/mL), as the effect of the single-dose TCZ administration decreased with decreasing TCZ concentration. The clinical relevance of these changes can be revealed when compared to the effect of rifampin (a

**FIGURE 11-3** Comparison of (a) simvastatin and (b) simvastatin acid metabolite. AUC change in rheumatoid arthritis patients (RA Pts) and in RA patients treated with tocilizumab (TCZ) rifampin, and grapefruit juice (GFJ) compared to healthy volunteers (HVs). Simvastatin was administered with water alone, 24 h after the last dose of 200 mL GFJ (3 times a day for 3 days) and 5 days after 600 mg rifampin daily treatment.

typical CYP3A4 inducer[34] and grapefruit juice (GFJ; a CYP3A4 inhibitor).[37] SIM $AUC_{0-\infty}$ was decreased by 87% after 5 daily doses of 600 mg rifampin,[34] and SIM $AUC_{0-\infty}$ was increased by ninefold after 3 days dosing of 200 mL GFJ three times daily.[37] The decrease in SIM $AUC_{0-\infty}$ upon initiation of TCZ (1 week postdosing) was much less than the change by rifampin (Figure 11-3a) and the lincrease in SIM $AUC_{0-\infty}$ increase after stopping of TCZ treatment (5 weeks postinfusion) was also much less than the change by GFJ (Figure 11-3b). A similar conclusion can also be drawn for the $AUC_{0-\infty}$ of SIM acid metabolite (Figure 11-3b). Interpretation of the findings of the TCZ DDDI assessments in the context of the effects of other well-known DDI perpetrators supports the recommendation that "the effect of tocilizumab on CYP enzymes may be clinically relevant for CYP450 substrates with narrow therapeutic index, where the dose is individually adjusted."[2]

# DRUG–DRUG INTERACTIONS FOR ETANERCEPT—A FUSION PROTEIN

JOAN KORTH-BRADLEY

The treatment of immune-mediated inflammatory diseases, such as rheumatoid arthritis, psoriasis, and psoriatic arthritis has been changed with the introduction of biological agents in the 1990s. Previously available biological agents, such as insulin, were replacements for endogenous proteins that were missing in patients with diabetes, while newer agents such as etanercept were constructs not found in nature. In this case study of drug–drug interaction assessments for etanercept, a fusion protein targeting tumor necrosis factor α (TNF-α) used in the treatment of several immune-mediated inflammatory diseases, background information about etanercept will be discussed, followed by a general assessment on the likelihood of drug interactions with fusion proteins such as etanercept and finally the results of specific etanercept–drug interaction investigations will be discussed.

## 12.1 ETANERCEPT BACKGROUND

Etanercept is a human tumor necrosis factor receptor (TNFR) p75 Fc fusion protein produced by recombinant DNA technology in a Chinese hamster ovary (CHO) mammalian cell expression system. It is a dimer of a chimeric protein genetically engineered by fusing the extracellular ligand binding domain of human tumor necrosis factor receptor 2 (TNFR2/p75) to the Fc domain of human immunoglobulin G1 (IgG1). The Fc component of etanercept contains the hinge, CH2 and CH3 regions, but not the CH1 region of IgG1. Etanercept has a molecular weight of approximately 150 kDa. It causes immune suppression by binding tumor necrosis factor, which is increased in patients with inflammatory diseases.[1]

Initially approved for the treatment of rheumatoid arthritis (RA), etanercept has subsequently received approval for the treatment of juvenile rheumatoid arthritis

*Pharmaceutical Sciences Encyclopedia: Drug Discovery, Development, and Manufacturing*,

(JRA), psoriatic arthritis (PsA), psoriasis, and ankylosing spondylitis (AS). It was also investigated for the treatment of congestive heart failure (CHF), without success. Initially, the approved dose was 25 mg administered by subcutaneous injection twice weekly. The dose for children was 0.4 mg/kg twice weekly. Subsequently, 50 mg administered weekly was also approved, as was 0.8 mg/kg administered once weekly in children.

After subcutaneous injection, etanercept is slowly absorbed into systemic circulation, with maximal concentration reached in 2 to 3 days. Dose proportionality has not been formally evaluated, but saturation of clearance is not apparent over the dosing range studied, and systemic exposure appears to be linear. Bioavailability after subcutaneous administration is 58%.[2] Bioequivalence of absorption was shown after administration of either liquid or reconstituted lyophilized etanercept to healthy volunteers.[3] The volume of distribution of etanercept is small. After administration of single subcutaneous etanercept doses in healthy subjects, the apparent volume of distribution was $12 \pm 6$ L.[4] In 3 subjects with RA, repeated samples of synovial fluid showed etanercept concentrations were similar to those observed in serum. Etanercept is slowly cleared from the body with a terminal half-life of 3 to 4 days. It is assumed that after binding of etanercept to TNF, the etanercept–TNF complex is then metabolized through peptide and amino acid pathways with either recycling of amino acids or elimination in bile and urine.[4] There was elimination of radioactivity observed in urine after administration of radiolabeled etanercept to patients and healthy subjects,[5] but almost no intact etanercept was observed in the collected urine.[6]

The potential impact of various demographic and disease characteristics on the pharmacokinetics of etanercept has been evaluated. A study of 30 healthy Japanese volunteers who received single subcutaneous 10-, 25-, or 50-mg doses of etanercept showed comparable pharmacokinetics with a similar group of healthy American volunteers.[6] A small pharmacokinetic study ($n = 6$) was performed in subjects with end stage renal disease requiring dialysis. The pharmacokinetics in these subjects was similar to subjects with psoriasis not requiring dialysis.[7] The pharmacokinetic profile of etanercept in subjects with RA showed parameters similar to those observed in healthy subjects.[8] Pharmacokinetics in subjects with AS were similar to those observed in subjects with RA.[9] The pharmacokinetics of etanercept were studied in 11 subjects with chronic CHF after repeated etanercept doses of 12 mg/m$^2$.[10] The pharmacokinetic results in subjects with CHF were similar to those observed in healthy subjects and in subjects with RA.

Several population pharmacokinetic analyses have been performed to further characterize etanercept pharmacokinetics. Lee and co-workers fit a one-compartment model to concentration data collected from 77 subjects who had received either 25- or 50-mg doses twice weekly for 24 weeks.[11] Significant covariates for apparent clearance were sex and race (white vs. nonwhite). White women had mean (95% confidence intervals) clearance estimates of 0.117 (0.108–0.130) L/h, and white men had clearance estimates of 0.138 (0.118–0.163) L/h; nonwhite patients had mean clearances that were 138% (104–160%) compared with white patients. Zhou and co-workers fit a two-compartment model to

concentration data collected from 10 studies, including 265 healthy subjects and patients with JRA and RA.[9] One of the studies had data after IV administration. The final model showed that age (<17 years) and body weight (<60 kg) were significant covariates for apparent clearance, which was lower compared with other subjects. The clearance in children (4 to 17 years of age) was lower than clearance in adults; however, when clearance values were adjusted for body weight, clearance was comparable with that of adults. A modest effect of the presence of RA on absorption was observed, and nonwhite individuals had larger central volumes of distribution, which disappeared if weight normalized. Finally, Nestorov's group fit a one-compartment model to data collected from three studies in 1077 patients with psoriasis.[12] Gender, weight, and time were significant covariates for apparent clearance and body weight for apparent volume of distribution. In contrast to what was observed in the previous analysis in patients with RA, in this analysis, the population mean (95% confidence interval) for clearance in women (0.148 L/h, 0.137–0.161 L/h) was higher than in men (0.129 L/h, 0.123–0.136 L/h). The finding of lower clearance with lower body weight may counteract the discrepancy. Apparent clearance increased over the first 4 weeks. With the exception of dosing for children <60 kg, none of the covariates identified is considered clinically significant or needing specific dosing.

## 12.2 MECHANISMS OF DRUG INTERACTIONS

Formal drug interaction studies were not performed during the initial clinical development of etanercept. It was believed that etanercept has little potential for causing drug interactions, or being influenced by administration of either inducers or inhibitors of important metabolic enzymes for other medications and thus drug interaction studies would not provide information about the metabolic fate of etanercept.

Parenteral administration excludes potential for absorption interactions with either food or other concomitantly administered medications. The volume of the injection is 1 mL when etanercept is administered to adults. It is unlikely that patients would want to combine other medications for simultaneous injection. Such combinations would not be recommended owing to potential physicochemical problems as well as simply too much volume.

Etanercept is a biological product. Methods to assess the extent of protein binding for small, synthetic molecules are not capable of adequately assessing protein binding for large molecules that are proteins themselves. It is believed there is relatively low potential for displacement reactions between etanercept and other medications that are highly protein bound.

As noted previously, it is assumed that after binding of etanercept to TNF, the complex is then metabolized through peptide and amino acid pathways with either recycling of amino acids or elimination in bile and urine. The cytochrome P450 system (CYP) and other commonly used metabolic pathways are not involved in the metabolism of etanercept, so there is little potential for metabolic drug interactions. The role of transporters in etanercept pharmacokinetics has not been studied.

Finally, etanercept is not believed to change biliary or urinary production and flow, so interactions associated with elimination are also not likely to occur. Information about metabolism and excretion, and thus potential for interaction, is obtained by studying the pharmacokinetics of drug in patients with isolated end organ dysfunction. In the case of etanercept, no evidence was obtained to suggest that either renal or hepatic failure alters elimination of the drug. A study of patients with severe sepsis received a single intravenous dose of etanercept to test whether etanercept had activity in this condition.[13] Serial serum concentrations were measured and, although not reported in the paper, no difference in concentrations in different subjects with different degrees of acute hepatic impairment or acute renal impairment.[5] As noted earlier, a study of subjects with chronic renal failure showed no difference in pharmacokinetics.

In the approximately 15 years since the development of etanercept, many more therapeutic proteins have been studied and guidelines for evaluation of the potential for drug interactions have been developed.[14] In addition to the various mechanisms by which drug interactions may occur already discussed, the importance of cytokine induction of important CYP enzymes has become better understood. Etanercept is not a cytokine and so again would not be expected to directly alter CYP activity. A potential indirect effect could be caused through inhibition of TNF-α by etanercept, but there have been no reports in the literature of interactions of this type. In conclusion, etanercept has a low likelihood of causing a drug interaction or being affected by other medications.

## 12.3 PHARMACODYNAMIC DRUG INTERACTIONS

Although etanercept may have a low potential for interactions from a pharmacokinetic perspective, pharmacodynamic interactions may occur as a result of its activity. It is always reasonable to evaluate the potential for interactions among medications that are commonly administered for the same indications. Rather than performing pharmacokinetic studies, researchers can collect safety and efficacy data as well as pharmacokinetic data in Phase II and III trials; the results are reviewed carefully for evidence of interactions.[15] This type of investigation was the basis for the recommendations that etanercept not be used concomitantly with anakinra,[16] abataept,[17] cyclophosphamide,[18] or sulfasalazine.[19] In each case, the patients receiving combination therapy had more serious adverse reactions, usually infections, than those subjects in the control group without benefit of improved efficacy.

In addition to too much immunosupression, etanercept may interfere with the desired response to vaccines. Patients exposed to varicella virus should temporarily discontinue etanercept and consider prophylactic treatment with varicella zoster immune globulin.[20] A study of patients with PsA showed that patients treated with etanercept or placebo had similar responses to pneumococcal vaccine.[21] Approximately 20% of patients failed to show a twofold response to any of the antigens. It was concluded that there was no increased risk of poor response with etanercept treatment given alone or with methotrexate.

## 12.4 RESULTS OF DRUG INTERACTION STUDIES WITH ETANERCEPT

Formal drug interaction studies have been performed to evaluate the interactions of etanercept with methotrexate, digoxin, and warfarin. Etanercept concentrations were also measured in clinical trials for patients with RA who were also treated with anakinra.

There was no mutual pharmacokinetic interaction between etanercept and warfarin.[22] In a nonrandomized, three-period study, 12 healthy male subjects received a single oral 25-mg dose of warfarin after an overnight fast, followed by twice-weekly 25-mg subcutaneous doses of etanercept for seven doses. The last dose of etanercept was administered concurrently with a second dose of warfarin. Serial blood samples for plasma warfarin concentration measurement and international normalized ratio (INR) assessment were collected before and up to 144 h after dose administration. Serial blood samples for serum etanercept concentration measurement were collected before and up to 60 h after the sixth dose and 264 h after the seventh dose. Etanercept did not affect the pharmacokinetics and pharmacodynamics of warfarin. All ratios of maximum serum concentration ($C_{max}$) and area under the serum concentration versus time curve (AUC) for pharmacokinetics (R- and S-enantiomers of warfarin) and INR fell within the confidence interval of 0.8 to 1.25. Warfarin also did not cause a clinically significant alteration in the pharmacokinetics of etanercept. In conclusion, coadministration of etanercept and warfarin would not be expected to change the pharmacokinetics of either medication; therefore, no dosage adjustment is needed in cases in which warfarin and etanercept are coadministered.

There was also no effect of coadministration of etanercept on the pharmacokinetics of digoxin.[23] In a crossover, open-label, nonrandomized, three-period study, 12 healthy male subjects received loading oral doses of digoxin 0.5 mg every 12 h on day 1 and 0.25 mg every 12 h on day 2, followed by a daily maintenance dose of 0.25 mg for a total of 27 days. Etanercept was administered as a twice weekly 25-mg subcutaneous dose beginning on day 9 and continuing up to day 37 for a total of 9 doses. All ratios of $C_{max}$ and AUC for pharmacokinetics of digoxin fell within the confidence interval of 0.8 to 1.25. Although not considered clinically relevant, the mean $C_{max}$ and AUC of etanercept were 4.2% and 12.5% lower, respectively, when etanercept was given with digoxin than when administered alone. There were no clinically relevant changes in the electrocardiogram parameters, and adverse events did not increase when both drugs were combined. In conclusion, there is no clinically relevant interaction between etanercept and digoxin, and both drugs can be safely coadministered without the need for a dosage adjustment.

The results from the population pharmacokinetic analysis demonstrated that the coadministration of methotrexate had no significant effect on the pharmacokinetics of etanercept in subjects with RA.[24] Using the population pharmacokinetic model previously described, which included data from healthy subjects and patients with RA and JRA, nine Bayesian-derived individual pharmacokinetic parameters were

estimated for 100 individuals, 50 receiving methotrexate and etanercept and 50 receiving etanercept alone. The patients had been randomly selected from the TEMPO trial[25] and each had had a single serum measurement collected after 24 weeks of treatment. The predicted weight-normalized CL values were $0.071 \pm 0.013$ and $0.072 \pm 0.011$ for the etanercept-treated patients and for the combination treated patients, respectively. Thus no dose adjustment of etanercept dosage is needed when coadministered with methotrexate.

The study of combined treatment of etanercept and anakinra mentioned previously[16] also collected blood samples for the measurement of anakinra and etanercept concentrations in plasma before dosing and then at 4, 12 and 24 weeks after the start of treatment. Although there was large intersubject variability, there appeared to be no difference in either anakinra or etanercept concentrations between those on combination therapy and those receiving etanercept alone.

There are references in the literature to an interaction between paclitaxel and etanercept, where coadministration of paclitaxel causes an increase in etanercept concentrations of 1.5-fold,[14,26] but the specifics of the interaction are not well described in the literature or in the prescribing information for any of the commercially available forms of paclitaxel.[27,28]

## 12.5 CONCLUSIONS

In conclusion, much more is known now about the potential for drug interaction involving therapeutic proteins than when etanercept was being developed. However, a systematic review of potential causes for drug interactions and careful review of safety and efficacy of studies where combinations of medications are used has been successful in identifying pharmacodynamic interactions so that potentially unsafe combinations of treatments can be avoided, even when pharmacokinetic interactions are unlikely.

# DRUG INTERACTIONS OF CYTOKINES AND ANTICYTOKINE THERAPEUTIC PROTEINS

J. GREG SLATTER, LARRY C. WIENKERS, and LESLIE J. DICKMANN

*If it were not for the great variability among individuals, medicine might as well be a science and not an art.*

Sir William Osler, 1892[1]

## 13.1 INTRODUCTION

The suppression of drug metabolism by proinflammatory cytokines and the relief of suppression by disease treatment are a current issue in the development of drug interaction labels for new biologic products. This topic has been the subject of a number of recent reviews that capture the history of related work as well as current regulatory and pharmaceutical industry thinking.[1–12] This chapter provides an overview of some recent data developed in industrially relevant preclinical models and outlines the pros and cons of these models with respect to the generation of actionable data–that is data that are robust enough to preclude the need for a clinical drug–disease interaction study, and/or a class label for a new cytokine or anticytokine therapeutic agent.

Because small molecule clearance mechanisms are suppressed by inflammation, proinflammatory cytokine treatment and/or active inflammatory disease may afford patient populations with impaired drug clearance.[6] As such, the effective treatment of inflammatory disease would be expected to normalize or "desuppress" drug clearance. When clearance is mediated by cytochromes P450 (CYP), suppression works in the same direction as CYP inhibition, leading to increased systemic exposure. In contrast, CYP desuppression increases CYP activity (similar to CYP induction), leading to lower drug concentrations. The caveat with desuppression is that the upper limit of the effect is the clearance

observed in healthy patients. The clinical literature that have accurately measured the magnitude of these effects are limited. Where clinical pharmacokinetic effects have been characterized, several drug labels appropriately note that small molecule clearance changes are possible when anti-inflammatory biologic agents or proinflammatory cytokines are coadministered with narrow therapeutic index small molecules that are cleared mainly by CYP enzymes (labels are reviewed in Ref. 5). Many pharma/biotech pharmacokinetics and drug metabolism labs are now discussing best practices for *in vitro* experiment design and interpretation, meaningful *in vitro* to *in vivo* correlations (IVIVC), and the design of suitable clinical investigations involving therapeutic proteins.[13,14]

## 13.2 CLINICAL RELEVANCE OF CYTOKINE-MEDIATED SUPPRESSION AND DESUPPRESSION OF ADME ENZYMES

When proinflammatory cytokine-mediated effects on CYPs are compared to induction and inhibition of CYPs by agents such as ketoconazole and rifampin, it is so far apparent that the clinical magnitude of these effects are relatively subtle. In many cases, small study populations have made it difficult to discern a clinically measurable effect on transcriptionally variable CYP isoenzymes. The magnitude of known clinical changes of therapeutic protein DDI, along with useful data on dosimetry and necessary mechanistic details are compiled in three useful tables published in Ref. 4.

### 13.2.1 Treatment with Interferons and Related Proinflammatory Agents

Clinical interest in the suppression of drug metabolism by inflammatory disease rose after the 1978 account of side effects in asthmatic children on theophylline during an influenza outbreak. Theophylline half-life increases averaged about twofold,[15] and this highlights that subtle disease-mediated changes in oral clearance can be clinically significant in narrow therapeutic index drugs. Shedlofsky et al.[16] showed that changes in theophylline and antipyrine clearance in healthy subjects could be elicited with lipopolysaccharide (LPS) endotoxin. Interferon-mediated suppression of CYP in influenza was proposed as a potential mechanism in a clinical study in healthy subjects that compared antipyrine clearance during influenza (78% of healthy value) and after administration of interferon A (85% of healthy value) or interferon B (85% of healthy value).[17]

Over the time period when disease-related CYP effects were first linked to interferons, these cytokines were also of interest as drug candidates. Type I interferons ($\alpha$2a, $\alpha$2b, $\beta$1a, $\beta$2b) are a key component of polytherapy of Hepatitis B and Hepatitis C viral infections (HBV and HCV), autoimmune diseases, and cancers, by virtue of their ability to elicit a host immune response. As a consequence, CYP suppression by interferons has been investigated largely clinically because combination therapy entails risk of higher exposure to concomitant, narrow therapeutic index CYP substrates.[18] *In vitro* studies and a variety of preclinical *in vivo* studies have also been undertaken to understand the mechanism of CYP suppression, relative to other

cytokines such as the interleukins. Flaman et al.[18] recently examined the mechanism of CYP3A4 suppression by interferon α in human hepatoma (HepG2) cells and demonstrated a time-dependent and physiologically relevant concentration-dependent decrease in CYP3A4 transcription at nontoxic concentrations of interferon α. They proposed that suppression was transcriptional and involved an interferon-mediated JAK1-STAT1 signaling cascade that is independent of ERK1/2 and p38 MAP kinases. Aitken and Morgan[19] investigated a type II interferon, interferon γ, and showed that it mediated isoform-specific effects on CYPs in human hepatocytes, with CYP1A2, 2A6, 2B6, and 3A4 activities being selectively suppressed in a nitric oxide–independent manner. Isoenzyme-specific upregulation and downregulation of CYPs by interferon α2b has also been observed at therapeutic concentrations in human hepatocyte coculture with Kupffer cells.[20] Kupffer cells are a contributor to cytokine-related signaling in the liver, and there is current interest in whether data from human hepatocyte/Kupffer cell cocultures are any more informative than hepatocytes alone, in terms of recapitulating *in vivo* acute phase response effects on CYPs.[20,21]

A variety of clinical studies on therapeutic interferons have revealed that probe substrate clearances were generally in the range of 85% to 40% relative to control values. Oral clearance decreases were generally less than twofold to threefold (50% to 33% of control values) and covered a variety of major CYP isoenzymes.[4] Accordingly, there are relatively few drug interactions listed in the product labels of interferons. Label warnings include use of interferon α2a and α2b with theophylline, the latter doubling theophylline levels. In 18 peginterferon α2b–naive chronic hepatitis C subjects on stable methadone maintenance therapy, mean methadone AUC increased by about 16% after 4 weeks of peginterferon α2b treatment and was about twofold higher in two subjects. In 22 HCV patients, peginterferon α2b caused a modest increase in clearance of a CYP2C8/9 probe substrate (mean increase 28%), a variable increase in clearance of a CYP2D6 probe substrate (mean increase 66% with 13 subjects increased, 5 subjects decreased, and 4 subject unchanged) and with no significant effect on CYP1A2 and CYP3A4 probe substrates.[5] With these counterintuitive increases in CYP substrate clearance, it is apparent that suppression of CYPs by the interferons used for HCV therapy is not a straightforward problem. Data from Nakai et al.[22] may explain the subtle effects and counterintuitive data because the authors have shown that suppression of drug-metabolizing enzymes increases with the progression of liver fibrosis in chronic HCV patients. Accordingly, when interferons are used successfully in the treatment of HCV infection, sustained virologic responses over time may reduce hepatic inflammation and therefore mitigate the suppressive effects of the proinflammatory cytokine treatments. This highlights the temporal efficacy-related aspects of this drug–disease interaction that make the quantitative *in vivo* extrapolation of *in vitro* data tenuous.

### 13.2.2 Treatment of Inflammatory Conditions through the Mitigation of Cytokine-Mediated Signaling

It is now well established that inflammation contributes to pathology in a wide range of diseases and that inflammation can also contribute to altered drug pharmacokinetics and pharmacodynamics.[11,23] For example, drug–disease interactions of

this sort have been described for HIV patients whose oral midazolam clearance was 50% (a twofold decrease) or 82% relative to that of healthy subjects.[24,25] Losartan oral clearance was unaffected by rheumatoid arthritis, but its active metabolite AUC was 40% of control in subjects with active arthritis.[26] In other examples, antipyrine clearance was impaired in sepsis,[27] and clozapine clearance was impaired in infection.[28,29]

Haas et al.[30] showed an inverse correlation of serum interleukin 6 (IL-6) with CYP3A activity in postsurgical patients, as measured by the Erythromycin Breath Test. Frye et al.[31] showed inverse correlations of CYP1A2- and CYP2C19-mediated probe substrate metabolism with serum IL-6 in patients with congestive heart failure, and Rivory et al.[32] showed a correlation of the acute phase marker, serum C-reactive protein (CRP), with the Erythromycin Breath Test in cancer patients. Advanced cancer patients with reduced clearance of docetaxel and elevated markers of inflammation experienced more severe adverse effects of chemotherapy.[33] Chen et al.[34] revealed a strong correlation between IL-6 concentrations and increased cyclosporine levels in six bone marrow transplant patients receiving a continuous cyclosporine infusion over the posttransplant interval. On average IL-6 increased to a maximum of 19.8-fold and CRP was elevated to a maximum of 8.8-fold. Cyclosporine levels increased by 3.60-fold at 4.83 days after the maximum IL-6 concentration. The Spearman rank order correlation $R^2$ for the correlation between $C_{\text{max IL-6}}$ and dose normalized $C_{\text{max CsA}}$ was 0.794. For the cyclosporine metabolite AM1, the correlation with $C_{\text{max IL-6}}$ was 0.975.[34] Taken together, these selected studies show how systemic manifestations of inflammation are correlated with CYP status and how CYP suppression could be a contributor to adverse events, especially during acute care polytherapy.

As the studies cited indicate, the magnitude of CYP effects can be mild. Accordingly, there are also studies that failed to reveal significant cytokine-mediated effects on CYPs, such as when arthritis treatment with sodium aurothiomalate, sulfasalazine or penicillamine had no significant effect on the CYP3A marker, urinary 6β-hydroxycortisol in rheumatoid arthritis patients.[35] Similarly, there was no difference in cyclosporine pharmacokinetics in elderly patients with and without arthritis.[36]

To date, the upper magnitude of inflammatory disease treatment effects on CYP-related drug metabolism appears to be in the range of onefold to fourfold, with most examples occurring at the low end of the range. Upper limits of CYP suppression could be better defined with adequately powered studies comparing probe substrate pharmacokinetics and inflammation biomarkers in patients with severe inflammatory disease, measured either against predisease status or age and sex matched healthy subjects. The Chen et al.[34] study on cyclosporine pharmacokinetics in transplant patients stands out as a good example of the value of this approach.

### 13.2.3 The Tocilizumab–Simvastatin Interaction

So far there is only one published clinical study investigating a drug–disease interaction involving cytokine desuppression by anticytokine therapy, the tocilizumab–

simvastatin interaction.[37] Rheumatoid arthritis patients were treated with the anti-IL6R monoclonal antibody, tocilizumab (Actemra™),[36] and simvastatin pharmacokinetics were measured before and after tocilizumab administration. Rheumatoid arthritis patients experienced an 2.3 fold and (43% of control) decrease in the plasma AUC of the CYP3A4 substrate simvastatin after an 10 mg/kg tocilizumab dose.[36,37] In comparison, in separate pharmacokinetic studies, the decreases in simvastatin AUC after treatment with the prototypical inducer rifampin were 7.2- and 11.1-fold.[38,39] The view that desuppression normalized but did not induce simvastatin oral clearance in tocilizumab-treated rheumatoid arthritis patients is supported by a simvastatin $AUC_{0-\infty}$ comparison across separate studies ($44.5 \pm 19$ ng·h/mL in tocilizumab-treated rheumatoid arthritis patients versus 29 ng·h/mL (range 8–56 ng∗h/mL) in healthy subjects).[37,39]

### 13.2.4 Can C-reactive Protein (CRP) and/or IL-6 Be Used to Predict the Clinical Magnitude of CYP Suppression and Desuppression?

Schmitt et al.[37] noted that the plasma concentration versus time profile of the acute phase reaction protein, serum CRP, "paralleled the time course of tocilizumab's effect on simvastatin pharmacokinetics." Production of CRP by hepatocytes and release into the systemic circulation is primarily elicited by IL-6 and to a lesser extent by IL-1β and tumor necrosis factor and is mediated by the transcription factors C/EBPβ and NF-κB.[40] This observation and the other independent correlations of CYP3A activity with CRP and IL-6 discussed earlier,[31,32] may indicate that initial and posttreatment CRP concentrations are a potential quantitative biomarker for overall hepatic inflammation of sufficient magnitude to suppress CYPs. Therefore, although it is widely acknowledged to be a variable inflammation biomarker, large changes in circulating CRP (and/or IL-6) may be inexpensively predictive of the clinical magnitude of suppression and/or desuppression of CYPs in adequately powered studies. Clinical data on other cytokine and anticytokine drugs will be needed to discern whether clinically measurable suppression and desuppression of CYP enzymes is possible in the absence of significant changes in CRP and IL-6. These data will be useful in understanding the relative magnitude of hypothetical "direct" effects of various individual cytokines on CYPs against a possible central role of transcriptional CYP suppression that occurs secondary to inflammation-related hepatocyte exposure to IL-6 and/or IL-1β.

## 13.3 MECHANISM

### 13.3.1 Cytokine-Mediated Suppression of CYPs

No single global mechanism has yet been identified that accounts for all inflammation-mediated changes for all drug-metabolizing enzymes. Ashino et al.[41] and others have conducted work related to the premise that blanket downregulation of pro-oxidant CYP oxidative pathways is hepatoprotective against immune-activation-related oxidative stress. Morgan[42] reviewed the complexities of possible adaptive

mechanisms for CYP suppression, including the relief of oxidative stress. In this insightful review, he posed some excellent "rational speculation" on why animals that experience inflammation might find it beneficial to suppress hepatic CYP enzymes. Transcriptional effects are the most investigated and may be coordinately regulated by a variety of different nuclear receptors and transcription factors[43] as they are in liver disease.[44] Because a number of cytokines mimic the effects of infection when injected *in vivo* or when incubated with hepatocytes in primary culture, downregulation of many CYP isoenzymes has been associated with elevated levels of a variety of cytokines.[19,42,45] Inflammation-related CYP suppression is mainly transcriptionally mediated, although posttranscriptional mechanisms have also been proposed.[46,47] Consequently, NF-κB-mediated regulation and related crosstalk with the pregnane X receptor (PXR, NR1I2) are often inferred, though an overall mechanism for suppression has not been fully elucidated.[48–52] Ghose et al.[53] proposed that suppression of many CYP isoenzymes may be mediated by inflammation-induced alteration of the subcellular location of retinoid X receptor α (RXRα), which is an obligate partner in heterodimeric nuclear receptors liver X receptor (LXR), farnesoid X receptor (FXR), retinoic acid receptor (RAR), constitutive androstane receptor (CAR), pregnane X receptor (PXR), and peroxisome proliferator activated receptor alpha (PPARα). Gu et al.[54] demonstrated direct interactions of NF-κB P65 with the DNA binding domain of retinoid X receptor alpha (RXRα). Taken together, these studies indicated that effects on RXRα are a potential explanation for cytokine-mediated suppressive effects that are observed across the spectrum of enzymes involved in steroid, lipid, bile acid, and drug metabolism.

A recent genomewide association study on CYP regulation profiled liver tissue from over 427 donors. The study revealed negative correlations between the expression of genes in a gene module related to the acute phase response (APR) and genes in an hepatic steroid and lipid metabolism gene module (see Figure 3 in Ref.[55]). Subtle downregulation of steroid and lipid metabolism, in consort with up-regulation of the APR related genes is apparently a core component of the hepatic response to systemic inflammation. This is illustrated in Figure13-1, for which supplemental data from Yang et al.[55] were used to plot pairwise correlations among mRNA of CYP3A4, PXR, IL-6, IL-1β, and the APR marker CRP. CYP3A4 expression in this population was correlated with many genes under the regulatory control of LXR, FXR, RAR, CAR, PXR, and PPARα. CYP3A4 was also weakly correlated with a variety of other hepatic acute phase markers associated with the APR.[55,56] It is attractive to speculate, based on these gene expression correlations, that hepatic inflammation is a covariate of basal CYP3A4 expression in human populations. If this were true, the dynamic range needed to discern these correlations in this population of liver donors may have been related to individual differences in disease state or suitability for transplant, hepatic inflammation related to the process of death and dying, and/or liver collection and preservation.

### 13.3.2 A Related Mechanism: Drug Binding to α1-Acid Glycoprotein

There is a second mechanism that alters small molecule pharmacokinetics in inflammatory diseases. Jamali and others have shown that drugs that bind

**FIGURE 13-1** Gene to gene mRNA expression correlations. CYP3A4, IL-6, and IL1β are correlated with a second CYP3A4 probe, the nuclear pregnane X receptor (PXR; gene name NR1I2) and the acute phase response marker, C-reactive protein (CRP). *Top row, CYP3A4 correlations*: (left) Two unique CYP3A4 probes were present on the array and show the expected high correlation between different probes for the same enzyme across the donor population; (middle) expected positive correlation between CYP3A4 and PXR (NR1I2) expression; (right) negative correlation between CYP3A4 and CRP. *Middle row, IL-6 correlations*: (left) Lack of correlation with CYP3A4; (middle) negative correlation between IL-6 and PXR (NR1i2) expression; (right) lack of correlation between IL-6 and CRP. *Bottom row IL-1β correlations*: (left) Dynamic range of IL-1β expression is narrower than IL-6 ($< \pm$ 10-fold), no correlation with CYP3A4; (middle) no correlation between IL-1β and PXR (NR1i2) expression; (right) no correlation between IL-1β and CRP. Plots prepared by Dr. Yudong He (Amgen Corp), from open access data at sagebase.org and data from Ref. 55.

extensively and exclusively to the acute phase reaction protein α1-acid glycoprotein (AAG) can exhibit inflammatory disease-dependent clearance.[11,23] A recent study on the kinase inhibitor vismodegib illustrates how modern biophysical techniques can be used to assess the role of AAG-binding-dependent pharmacokinetics in patient populations.[57] The AAG drug–disease interaction mainly occurs with basic oral drugs that have intermediate to high extraction ratios, such as verapamil and β-blockers.[58] Most AAG correlations with drug clearance were developed using *in vivo* experiments in rats or mice, for which treatment-mediated relief of experimental inflammation was accomplished with ketoprofen and infliximab.[59,60] In these cases, binding to elevated AAG may work in consort with inflammation-impaired CYP-mediated clearance to increase drug exposure. Accordingly, changes in oral clearance of AAG-binding drugs with rate-limiting CYP-mediated metabolism may be greater than in drugs that do not bind AAG. For example, rheumatoid arthritis resulted in a fourfold increase in total verapamil AUC, relative to control subjects.[58]

## 13.4 CAN PRECLINICAL MODELS BE USED TO PREDICT CLINICAL SUPPRESSION OR DESUPPRESSION?

### 13.4.1 Cytokine Effects in Hepatocyte Culture: Studies on IL-6

Human hepatocytes are an *in vitro* model of choice for investigating cytokine effects on CYPs.[21,19,61] IL-6 is the most studied cytokine to date and is known to decrease CYP mRNA and the activities of major human CYP isoenzymes.[19] For the interleukins, virtually all *in vitro* hepatocyte studies conducted before 2010 were conducted at cytokine concentrations that were much higher than human serum cytokine concentrations. For example, in healthy individuals, serum IL-6 concentrations range from 1.3 to 10.3 pg/mL and are increased to 2.6–123 pg/mL in inflammatory diseases.[61]

Our laboratory carried out an analysis of CYP regulation by IL-6 and desuppression of CYP by an anti-IL-6 monoclonal antibody.[61] IL-6 was chosen as a model cytokine to define industrially relevant pros and cons of *in vitro* experimentation on cytokine-mediated suppression of CYPs in primary human hepatocytes. IL-6 was also selected because well-designed clinical and related *in vitro* work became the foundation of the tocilizumab drug–disease–drug interaction label[37] and because of the multiple roles of IL-6 in liver physiology.[62] mRNA expression of diverse drug metabolizing enzymes and CYP1A2 and 3A4 activities were measured.

Cytokines and antibodies from commercial vendors required special characterization that is outside of the realm of standard small molecule *in vitro* drug metabolism protocols. For example: Experiments were benchmarked to physiologically relevant serum cytokine concentrations. Binding affinities of monoclonal antibodies for their targets were characterized and compared to the affinity of the cytokine for its receptor. Lastly, the expression of relevant cytokine receptors on hepatocytes, and the cytokine-mediated generation of acute phase proteins (serum amyloid A and/or CRP) were followed through the course of the experiment.[61,63]

**FIGURE 13-2** Single donor data showing the dose-response of human hepatocytes to interleukin 6 (IL-6). mRNA expression of CYP3A4 is compared to mRNA of the acute phase response marker C-reactive protein (CRP) and mRNA expression of the IL-6 receptor. Dashed vertical bars show the normal physiological range of IL-6 and IL-1β serum concentrations in health and disease. Selected data from Ref. 61 were replotted with permission.

Across the spectrum of major drug metabolizing enzymes, CYP3A4 was the most sensitive to suppression by IL-6 and CYP1As were the least sensitive. The $EC_{50}$ values of many CYP isoenzymes were above the range of physiological IL-6 concentrations. The dynamic range of IL-6 responsiveness was determined in human hepatocytes and compared to the development of the hepatocyte APR, as measured by CRP production. In Figure13-2, a single hepatocyte donor dose-response to IL-6 shows that CYP suppression, CRP production, and IL-6 receptor (IL-6R) downregulation all occurred within or near the physiological range of serum IL-6 concentrations. This suggests two intriguing possibilities. First, that the hepatocytes in this model corroborate clinical indications that CYP suppression and the APR are correlated, indicating that CRP could be a bona fide biomarker of CYP suppression and desuppression in a large clinical population. Second, IL-6R downregulation may indicate an adaptive and/or self-limiting response to sustained cytokine exposure, and this could translate into the relatively modest downregulation of the CYP isoenzymes that has been observed clinically to date.

We also investigated the dynamic range of inflammation effects on CYP expression *in vitro* by studying cytokine-mediated CYP suppression during sustained induction pressure. Rifampin and omeprazole were used to induce CYP3A4 and CYP1A2, respectively. Both inducers shifted the IL-6 dose-response curve to the right, affording new $EC_{50}$ values that were well above the physiologically relevant range of IL-6 concentrations. Therefore, at least *in vitro*, CYP suppression by

cytokines may not necessarily overcome CYP induction by concomitant administration of a CYP inducer. The effect of CYP induction and suppression in rodents *in vivo* has been studied,[64] but a definitive study on the magnitude of CYP induction in inflammatory disease patients, relative to healthy individuals, could not be found.

No *in vitro* experiments have yet addressed the antibody-mediated abrogation of IL-6-mediated suppression of CYP that is the basis of the tocilizumab–simvastatin interaction. In human hepatocytes, an anti-IL-6 monoclonal antibody shifted the IL-6 dose-response curve for suppression of CYP3A4 activity to the right. Although this expected result indicated that the human hepatocyte model can indeed measure desuppression, the magnitude of the effect was a consequence of a long list of experimental variables, including antibody concentration and the competing affinities of antibodies, cytokine ligands, and their receptors.

Overall, these data illustrated that an individual cytokine can be studied in hepatocytes *in vitro* and can afford quantitative CYP suppression and desuppression data. However, these data represent only a small component of the complicated biology of the APR and/or chronic inflammation in the intact liver. This limits the value of the model for quantitative prediction of clinical drug–disease interactions related to CYP suppression and desuppression.

### 13.4.2 Is Interleukin-6 Always Involved When Hepatic CYP Suppression Occurs?

IL-6 is secreted by several different cell types, including T-cells, osteoblasts, and macrophages such as Kupffer cells in the liver. Acting via the IL-6 receptor on hepatocytes, IL-6 uniquely mediates diverse hepatic effects that include the APR, hepatic regeneration, and decreases in apoptosis and necrosis.[62] Tocilizumab efficacy data[65] have shown that the IL-6/IL-6R axis is a valid target for the treatment of rheumatoid arthritis. Similarly, the tocilizumab–simvastatin interaction has illustrated that IL-6 is also a key mediator of inflammatory disease manifestations in the liver.[37] Many other cytokines have been shown to cause CYP suppression *in vitro* (interferons, IL-1, IL-2, IL-10, TNF, etc.), yet the diverse roles of IL-6 in the liver may (or may not) render it preeminent among all cytokines as a biomarker or rate-limiting mediator of a clinically measurable effect. As such, cytokine combination experiments *in vitro* might help determine which cytokines are key drivers of hepatic CYP responses to systemic inflammation.

### 13.4.3 Recapitulating Hepatic Inflammation *in vitro* with Cytokine Combinations

The evaluation of a single cytokine in isolation in hepatocyte culture *in vitro* has little chance of recapitulating the complexity of acute or chronic inflammation in the liver *in vivo*. Many studies have examined the effect of LPS endotoxin,[66,67] and others have systematically dissected components of the APR through the study of individual cytokines.[19,21,68–70] To probe whether two clinically significant cytokines could act additively or synergistically *in vitro*, we examined the effects of

IL-1β alone and in combination with IL-6, on drug-metabolizing enzymes in human hepatocytes.[63,71,72]

It has been shown that IL-1β can suppress hepatic drug-metabolizing enzyme and transporter levels, implying a role of IL-1β in CYP suppression.[19,41] As with IL-6, isoform-specific differences have been observed in CYP suppression in IL-1β-treated hepatocytes *in vitro*.[19,46] However, all studies conducted to date have examined supraphysiologic concentrations of IL-1β relative to physiologically relevant serum concentrations.

Like IL-6, IL-1β alone suppressed mRNA of several CYP isoenzymes, with $EC_{50}$ values that differed by isoenzyme.[63] $EC_{50}$ values of IL-1β were markedly higher than those of IL-6. IL-1β also caused upregulation of CRP and downregulation of IL-6R mRNA. These two events occurred near the physiological range of serum IL-1β concentrations.[73,74] As shown in Figure13-3,[63] IL-1β and IL-6 combinations at concentrations from 1 to 100 pg/mL in human hepatocytes demonstrate that IL-6 was the dominant cytokine in terms of increases in CRP mRNA as well as decreases in CYP3A4 and 2B6 mRNA.

The effects of pairwise or ternary combinations of other cytokines on CYPs, when benchmarked to physiological serum cytokine concentrations, may inform

**FIGURE 13-3** A comparison of the acute phase reactant (a) C-reactive protein (CRP), (b) CYP2B6, (c) CYP2C9, and (d) CYP3A4 mRNA responses in human hepatocytes treated with interleukin 6 (IL-6) and IL-1β. Asterisk: a p-value <0.05 when compared to untreated cells. Adapted from Ref. 63, Figures 2 and 3 with permission.

which cytokines are dominant in effects on CYP in isolated hepatocytes. These experiments may help in the development of a mechanistic understanding of which cytokines are the most important, even if this approach is certain to fall short of the *in vitro* reconstitution of human disease in liver. Important data in these investigations are the presence of relevant cytokine receptors on hepatocytes, the measurement of CRP and the downregulation of relevant cytokine receptors. Cosgrove et al.[75] developed a cytokine combination matrix and coincubated major cytokines with drugs known to elicit idiosyncrasy with human hepatocytes. The study evaluated synergy among major cytokines in the manifestation of drug-induced hepatocellular toxicity and may represent a useful approach for the systematic assessment of effects of ternary cytokine combinations on CYP suppression.

### 13.4.4 CYP Suppression and Desuppression in Murine Models of Inflammatory Disease *In Vivo*

There are many published studies on suppression of drug-metabolizing enzymes by cytokines in rodent models. A general inflammatory stimulus from bacterial LPS in preclinical *in vivo* models suppresses CYP probe substrate clearances generally by onefold to twofold.[66] However, there are relatively few studies on disease treatment effects on CYP suppression. Piquette-Miller and Jamali[59] studied nonsteroidal anti-inflammatory drug (NSAID) treatment effects on propranolol pharmacokinetics in severe adjuvant arthritis in rats. They investigated CYP markers, protein binding, and cytokine levels for this basic, AAG-binding drug. Ling and Jamali[60] studied the effect of the anti-TNF monoclonal antibody infliximab on the resolution of early adjuvant arthritis in rats by examining effects on CYPs, inflammation markers, and pharmacokinetics of the AAG-binding molecule verapamil. Ashino et al.[76] studied the effect of a murine anti-IL-6 monoclonal antibody treatment on arthritis in a transgenic mouse arthritis model. The effects of disease and treatment on CYP activity and expression were measured. In the Ashino study, IL-6 was markedly upregulated and CYP3A was the most sensitive CYP isoenzyme to suppression in arthritic rats. CYP3A protein content fell to 60% of that in nonarthritic transgenic rats, and an anti-IL-6 antibody normalized this response.

The collagen antibody-induced arthritis (CAIA) mouse model of rheumatoid arthritis is used to screen therapeutic candidates. In this model, arthritis is induced by initial administration of a monoclonal antibody cocktail directed toward epitopes in collagen type II that are highly autoantigenic, followed by administration of an endotoxin such as LPS.[77] Arthritis is induced within a week of initiation, with the severity of arthritis corresponding to the dose of monoclonal antibody cocktail.[78]

We adopted murine CAIA as a potential fast-turnaround model that might help in the development of *in vitro* to *in vivo* correlations.[79,80] On days 5 and 7 after initiation of the CAIA protocol, serum IL-1β, IL-6, and the APR marker serum amyloid A (SAA) were significantly elevated (Figure13-4), whereas both IL-2 and TNF-α were below limits of quantitation (not shown in the figure). Hepatic CYP mRNA levels were generally downregulated in the CAIA model, although CYP1b1, 2d9, and 3a13 were upregulated, relative to arthritis-naive animals at day 5 of treatment.

**FIGURE 13-4** Serum cytokine and hepatic serum amyloid A (SAA) levels measured in naive, lipopolysaccharide (LPS) treated and collagen antibody-induced arthritis (CAIA). mice (a) Interleuken 1β (IL-1β) protein, (b) IL-6 protein, and (c) SAA mRNA. Serum IL-2 and tumor necrosis factor α were below the limits of quantitation. Adapted from Ref. 79 with permission.

CYP1a2, 2c29, 2b9, and 3a11 mRNA were significantly downregulated to 36%, 29%, 44%, and 45% of naive values at day 5, whereas CYP2e1 levels were unchanged (Table13-1).[79,80] These data were consistent with results obtained using a transgenic mouse model of arthritis where CYP2c29 and CYP3a11 hepatic mRNA were downregulated to 75% and 45%, respectively, compared to wild type animals.[76] Other models are known to afford strain- and isoform-dependent CYP suppression data, such as in a bacterial LPS model of acute inflammation.[67] Taken together, these studies indicate that the direction and magnitude of changes in hepatic CYP enzymes in preclinical inflammation models depend on both the model of inflammation and the mouse strain used.

Intrinsic clearance data obtained using hepatic S9 with phenacetin, bupropion, diclofenac, dextromethorphan, and testosterone CYP probe substrate activities suggests that the maximum decrease in CYP activity in the CAIA model is approximately twofold (Figure13-5).[79,80] With the exception of dextromethorphan, the CAIA day 5 group and the LPS day 5 group had nearly identical profiles. This suggested that the observed decreases in the CAIA day 5 intrinsic clearance may be due to the administration of LPS alone and not the development of CAIA. Indeed, paw swelling in the CAIA model did not correlate with CYP suppression because CAIA

**$p < 0.05$ when compared to the respective LPS counterpart.
CAIA: collagen antibody-induced arthritis; IL: interleukin; LPS: bacterial lipopolysaccharide; POR: P450 oxidoreductase; SAA: serum amyloid A.

day 5 mice had, on average, a clinical score of 2.6 (out of 16) while the CAIA day 7 mice had an average score of 6.4. The differences observed between day 5 and day 7 for CYP suppression, cytokine markers levels, and disease severity show that this model is time dependent. The CAIA model measured maximum CYP suppression

**FIGURE 13-5** *In vitro* intrinsic clearance ($CL_{int}$) of several cytochrome CYP substrates in naive, lipopolysaccharide (LPS) treated and collagen antibody-induced arthritis (CAIA) mice. Values were obtained from pooled S9 fractions ($n = 8$ animals/group). Eadie-Hofstee plots indicated a multiple enzyme system for acetaminophen and 6β-hydroxytestosterone clearance. Changes in $CL_{int}$ reflected changes in both $V_{max}$ and $K_m$. Adapted from Ref. 79 with permission.

that was in the same general range as other murine models. However, aside for a short experiment cycle time, there were no compelling advantages over other arthritis models.

### 13.4.5 *In Vivo*/*In Vitro* Similarities and Differences between the CAIA Model and Cultured Mouse Hepatocytes Treated with a Cytokine Cocktail

Serum cytokine levels from the CAIA study were used as a guide for experiments on CYP suppression in mouse hepatocyte culture. While some CYP isoforms (CYP1a2, 2b9, 2c29, and 3a11) were in agreement in terms of magnitude and direction of suppression in both the *in vitro* and *in vivo* models, several isoforms (CYP2d9, 2e1, 3a13) were not (Table13-1).[79,80] Although this *in vitro*/*in vivo* comparison was rudimentary, it highlights the difficulty in properly reconstructing a complex inflammatory disease state in an *in vitro* hepatocyte model.

### 13.4.6 Are *In Vitro* Data Adequate to Preclude the Need for a Clinical DDI Study?

The pros of investigating cytokine-mediated effects on CYP expression in human hepatocytes are that *in vitro* experimentation affords quantitative data showing that ablating a particular inflammatory cytokine might de-suppress/normalize CYP activity. As such, mechanisms can be studied and hypotheses developed using this mainstream industrial technology.[61] However, it is at least technically challenging if not impossible, to accurately re-create an inflammatory disease state in hepatocytes *in vitro* and then treat it. This would be a crucial foundation for a clinically relevant and actionable *in vitro-in vivo* extrapolation. The single cytokine approach in hepatocytes is not likely to quantitatively predict subtle disease treatment effects on CYPs in humans *in vivo*. The diverse variables that are not controlled in hepatocytes include relevant hepatic cytokine concentrations, time-dependent adaptive response mechanisms like cytokine receptor downregulation, the absence of other interacting cytokines, the absence (or unquantified presence) of crucial cell types like Kupffer cells in primary hepatocyte culture, and of course the nuances of patient and disease-specific aspects of inflammatory disease.[61] Other models, such as Kupffer cell coculture may, theoretically, better recapitulate cytokine effects in whole liver. However, CYP3A suppression by IL-1β and IL-6 was not significantly altered by the addition of Kupffer cells in the first report of the application of this model to CYP suppression.[21] As such, human hepatocyte coculture is still in development, and the benefits and limitations of the technique for the study of cytokine-mediated suppression of CYPs have not been established.

Attempts are under way to simulate human pharmacokinetic outcomes based on currently available *in vitro* and *in vivo* data on IL-6. For example, cyclosporine pharmacokinetics and IL-6 concentrations in transplant patients[20] and *in vitro* human hepatocyte data from Aitken and Morgan[19] were used with a simCYP minimal physiologically based pharmacokiuetic (PBPK) model to retrospectively

predict a 2-5-fold increase in cyclosporine levels, against an actual 2-7-fold change.[81] Kenny[82] tested *in vitro* drug–drug interaction calculations using human hepatocyte data on IL-6-mediated suppression of CYP3A4 to calculate $K_i$ and $k_{\text{inact}}$ values. Population simulations were developed via simCYP using these *in vitro* data, along with clinical IL-6 and simvastatin concentrations from Schmitt et al.[37] to retrospectively simulate the magnitude of the tocilizumab–simvastatin interaction at low and high systemic IL-6 concentrations. They confirmed that IL-6 was a key variable in the interaction because closer predictions were obtained at higher IL-6 serum concentrations. More examples of clinically measurable effects of diverse cytokines and related therapeutic proteins on small molecule pharmacokinetics are needed before the potential merits of predictions based on preclinical *in vitro* experiments can be established for cytokines other than IL-6.

## 13.5 CURRENT REGULATORY PERSPECTIVE

The tocilizumab–simvastatin interaction was an important event from a regulatory perspective. The clinical observation of increased simvastatin oral clearance after tocilizumab treatment in patients with rheumatoid arthritis, along with some related *in vitro* characterization of IL-6 effects on CYPs in human hepatocytes, afforded a drug interaction label recommending caution for tocilizumab use with narrow therapeutic index CYP substrates.[4] Subsequently, regulatory authorities have requested *in vitro* and/or *in vivo* study data for other cytokine-modulating biologics such as golimumab[5] and for some therapeutic proteins that do not have direct connections to inflammatory disease. A science-driven article by regulatory scientists at the FDA on therapeutic protein–drug interactions (TP-DIs) was published recently,[5] and elements of that paper have reappeared in the revised draft drug interaction guidance that was issued for comment in 2012.[83] For cytokines or cytokine modulators, the new draft guidance advocates clinical investigation in targeted patient populations using probe substrates or probe substrate cocktails. Consistent with the complexities outlined in this chapter, the draft guidance also states that *in vitro* or animal studies have limited value in the qualitative and quantitative projection of clinical interactions because translation of *in vitro* to *in vivo* and animal to human results to date have been inconsistent.[83]

## 13.6 CLINICAL OPTIONS

Drug–disease interactions associated with an inflammatory disease could be investigated in a compound independent way by comparing CYP probe clearances in adequate numbers of patients with a given disease, against age- and sex-matched healthy controls. This would help establish the absolute upper magnitude of drug-metabolizing enzyme suppression for a given disease state. For disease treatment effects on CYP-mediated metabolism, midazolam AUC could be compared before and after treatment with the biologic agent. Alternatively, if it is thought that

CYP3A4 may not be the most sensitive CYP isoenzyme, a CYP probe cocktail approach may be pursued in a similar fashion.[84] To date, the study conducted by Roche on the tocilizumab–simvastatin interaction has a hallmark design, as it included data on the biomarkers IL-6 and CRP and included two sampling points after the administration of the long half-life antibody.[37] Whether the 80–125% confidence intervals employed in the tocilizumab–simvastatin interaction study to discern a clinically measurable interaction are appropriate for other compounds or diseases is open to discussion. Alternatively, confidence intervals could be set in a case-by-case fashion, possibly based on statistical assessment of treatment-induced changes in inflammatory disease severity biomarkers such as CRP, known population pharmacokinetic norms for narrow therapeutic index victim drugs in health and disease states, or variability in the expression of CYPs of interest.

In most cases, therapeutic protein drug–disease interaction studies will need to be conducted in the target population and are complicated by the long duration of the effects of most therapeutic antibodies. These and other factors may place practical limitations on the number of treatment arms in the study and may exclude some simple DDI study designs. Some study design options for DDI are overviewed in Huang et al.[5] When a cotherapy is likely to be employed extensively in the intended clinical population and plasma concentrations of the concomitant medication are monitored in larger clinical trials, a population pharmacokinetics–based approach may discern a measurable change in exposure to a select victim drug.

Industry scientists and regulators alike are interested in knowing whether *in vitro* data will ever be understood well enough to be used to develop a therapeutic protein drug interaction label that will effectively protect patients and inform healthcare practitioners. New therapeutic cytokines, anticytokine antibodies, and other biologic agents may have direct effects on CYP expression in hepatocytes, or indirect effects via hepatic manifestations of systemic inflammation, or both. It will continue to be difficult to rule out the need for a clinical pharmacokinetic study based on *in vitro* data alone because current *in vitro* models entail risk of false positive or false negative data and expected clinical effects are mild relative to classical CYP inducers and inhibitors.

The alternative is to proceed directly to clinical investigation. Some factors in determining the need for a clinical study might include a lack of direct effect on CYP3A4 in hepatocytes *in vitro* but might also consider whether relevant cytokine receptors are present on hepatocytes and whether large changes in systemic concentrations of inflammatory markers or APR proteins are expected in the target patient population. A risk-based, case-by-case approach is advised.

## 13.7 CONCLUSIONS

The chapter focused on how inflammatory disease can affect the expression of CYPs and other drug-metabolizing enzymes. In particular, clinical experience with inflammation-related effects on drug metabolism was reconciled with the *in vitro*

and *in vivo* models that could be used to model or predict the effects of disease, or cytokine/anticytokine treatments on drug metabolism. Recent work was used to illustrate the pros and cons of preclinical experimentation and to make recommendations with respect to actionable approaches to the development of a robust and informative drug interaction label.

# DRUG INTERACTIONS FOR GROWTH FACTORS AND HORMONES

YOW-MING C. WANG and TARUNDEEP KAKKAR

## 14.1 INTRODUCTION

According to the dictionary, the definition of *growth factor* is any of various proteins that promote the growth, organization, and maintenance of cells and tissues. And, the definition of *hormones* is any of various internally secreted compounds that affect the functions of specifically receptive organs or tissues when transported to them by the body fluids. Many of the proteins discussed in other chapters of this book, such as interferons and cytokines, may also be regarded as growth factors or hormones by these definitions. This chapter will discuss the traditional growth factors, primarily hematopoietic growth factors, and hormones, primarily growth hormones and glucagon.

The clinical applications of biotechnology-derived products began with growth factors and hormones in the 1980s. Two decades later, growth factors and hormones ranked the second and the third, respectively, of the top biologic drugs in terms of the U.S. sales[1] only behind therapeutic monoclonal antibodies. The total sales of growth factors and hormones combined accounted for approximately $20 billion (about $10 billion each).

In the growth factor category, epoetin α (recombinant human erythropoietin; rhEPO) approved by the U.S. Food and Drug Administration (FDA) in 1989 represents the first commercially available recombinant growth factor.[2] Filgrastim (recombinant human granulocyte colony stimulating factor, G-CSF) followed closely with an FDA approval in 1991. Subsequently, improvements to these recombinant human growth factors, by hyperglycosylation in the case of darbepoetin α[2,3] and by pegylation in the case of pegfilgrastim[4–6] and methoxy polyethylene glycol-epoetin β,[7,8] resulted in new generations of recombinant proteins with a longer

elimination half-life, enabling less frequent dose administration than the first-generation products. Palifermin (recombinant human keratinocyte growth factor; rhKGF) and romiplostim (a thrombopoietin stimulating agent) are growth factors that were approved in the past 10 years. These growth factors made substantial contributions to the therapeutic treatment of several chronic conditions.

Hormones, as a class, consist of a vast range of compounds to cover various ailments, and many have been on the market for decades. Most of the marketed drugs are of synthetic origin, including sex hormones such as estrogens, progesterone, thyroid hormone, and corticosteroids such as betamethasone. In 1960, the FDA approved Lilly's recombinant glucagon, which came more than 30 years after Murlin hypothesized that a hormone with a blood sugar–raising effect was present in the insulin product of low purity in 1923.[9] The first synthetic growth hormone, called somatrem, was developed in 1980s by Genentech in collaboration with a Swedish pharmaceutical company (Kabi), which commercialized the human growth hormone harvested and purified from cadavers.[10] The recombinant growth hormone somatropin, on the market now, is manufactured by an improved method.[10] Today, multiple recombinant human growth hormone and recombinant glucagon products are commercially available globally. Pegvisomant, a growth hormone analog and growth hormone receptor antagonist, was approved by European Medicines Agency (EMA) and the FDA in 2002 and 2003, respectively.

Pharmacokinetics (PK) drug interaction studies were not conducted as part of the clinical drug development program and did not play a role in the regulatory decision for many of the recombinant growth factors and hormone products. The PK drug interaction issue has been deemed unique to the small molecule chemical drugs and not of concern to the biotherapeutic agents because such agents are catabolized by proteolytic enzymes and do not share the metabolic pathways responsible for the *in vivo* disposition of small molecule drugs. Consequently, the understanding of PK drug interactions, or lack thereof, for these products primarily came from clinical experience in patient care over time and research conducted after the approval of marketing authorizations that was done to address these patient care findings.

Administration of two drugs indicated for treating the same disease condition is expected to show pharmacodynamic drug interactions because of additive or synergistic effects; often this type of drug interaction is factored into the study design and monitored during clinical trials and clinical use. For instance, romiplostim administration enables a reduction in the use of corticosteroids in treatment of thrombocytopenia, and the pharmacodynamic synergism of sex hormones is the basis for the use of follitropin α in combination with other agents to stimulate ovulation (e.g., human chorionic gonadotropin, clomiphene citrate) to potentiate the follicular response. This type of "polypharmacy" for additive therapeutic effect is not discussed in this chapter.

For many of the recombinant technology derived hormone products such as gonadotropins (luteinizing hormone, follicle-stimulating hormone, and human chorionic gonadotropin), minimal information is available in the literature and on product labels regarding drug interactions. We have opted to not discuss insulin because many drugs interact with insulin pharmacodynamically; some drugs alter the blood

glucose control and some drugs affect insulin sensitivity, which necessitate insulin dose adjustment. On the other hand, few reports on drug interaction involve insulin as a perpetrator even though in *in vitro* systems insulin has been implicated in modulating the expression of hepatic enzymes via its engagement in a multitude of cellular signaling pathways.

The focus of this chapter is on four recombinant growth factors products (erythropoietins, G-CSF, KGF, and thrombopoietins) and three hormone products (glucagon, somatropin, and pegvisomant). We compiled the information related to drug interactions found in scientific publications and regulatory agency approved labeling documents. The referenced U.S. prescribing information (PI) can be found at the Drugs@FDA website, and the European summary of product characteristics (SPC) can be found on the EMA's website for European public assessment reports (EPARs) by keyword search, using the international nonproprietary name (INN). In addition to the postings on regulatory agencies' websites, manufacturers and other interest groups also post up-to-date labeling documents on their product websites. Readers are referred to these online resources for the product labeling information cited in this chapter.

## 14.2 GROWTH FACTORS

### 14.2.1 Erythropoiesis-Stimulating Agents

Multiple commercial recombinant erythropoiesis-stimulating agents (ESAs)[2] are produced in Chinese hamster ovary (CHO) cells using recombinant DNA technology. They stimulate erythropoiesis by the same mechanism as the endogenous erythropoietin[11,12] and are indicated for treatment of anemia due to chronic kidney disease or chemotherapy. With the identical amino acid sequence as the natural erythropoietin produced by the kidney, epoetin α has 165 amino acids and a molecular weight (MW) of 30 kDa. Darbepoetin α, a second-generation ESA (MW 37 kDa), has two additional *N*-linked oligosaccharide chains compared to epoetin α, resulting in a prolonged terminal elimination half-life. The third-generation ESA product manufactured by Roche is methoxy polyethylene glycol (PEG)-epoetin β (MW 60 kDa), which differs from epoetin β in that PEG is covalently linked to some of the lysine residues in rhEPO, which also leads to a reduced clearance and a prolonged half-life. The prolonged half-life for these new ESAs afforded greater *in vivo* activity, despite the decrease of *in vitro* potency when compared to their respective first-generation counterpart. Other epoetins (e.g., epoetin β, epoetin δ, epoetin ζ) may have some structural differences from epoetin α and may or may not have differences in the biological activities.

The SPCs of epoetin α and darbepoetin α mentioned a potential for an interaction with substances that are highly bound to red blood cells, such as cyclosporine and tacrolimus, and recommended monitoring of the blood levels of the concomitant medications for assessment of potential dosage adjustment as the hemoglobin rises. Other implications of ESAs on clinical management of patients have been

reported where the observed interactions are primarily results of the pharmacodynamic effects of the ESAs. One example is the effect of ESA on the hemoglobin A1C level.[13] Hemoglobin A1C is a measure of the amount of glycosylated hemoglobin in the blood and is a commonly accepted indicator of the long-term glycemic control in diabetic patients.[14,15] But, its level depends on the number of circulating erythrocytes and the duration of red blood cells in circulation because glucose binding to hemoglobin occurs continuously during the life span of a red blood cell.[16] The hemoglobin A1C level decreases on initiation of ESAs and increases on discontinuation of ESA treatment; however, the glucose levels were reported to be stable. These data indicate that caution should be applied in the use of hemoglobin A1C level in patients who are initiating ESA treatment or in those whose ESA doses are being adjusted. Another example occurred in a German multicenter rhEPO trial,[17] where stroke patients receiving rhEPO after tissue plasminogen activator (tPA)-induced thrombolysis appeared to have increased mortality. A subsequent investigation in the mouse cerebral artery occlusion model suggested interaction of t-PA with EPO at the blood–brain interface–that is, promotion of vascular permeability and extracellular matrix breakdown may account for the unfavorable observation. As such, the authors concluded that after t-PA-induced thrombolysis, the use of EPO may not be suitable.[17] This hypothesis will need to be verified with additional studies.

### 14.2.2 Granulocyte Colony Stimulating Factor

Filgrastim, pegfilgrastim, and lenograstim are three commercially available G-CSF products. Filgrastim is a nonglycosylated recombinant human G-CSF (rhG-CSF) produced by *E. coli* containing 175 amino acids (MW 19 kDa). Pegfilgrastim is the pegylated filgrastim (MW 39 kDa), with a 20 kDa mono-methoxy-polyethylene glycol molecule covalently bound to the *N*-terminal methionyl residue of filgrastim. Lenograstim, a glycosylated rhG-CSF product, produced by CHO cells with 174 amino acids (MW 19 kDa), is approved globally outside the United States. Barring minor differences, these products are indicated for the treatment of neutropenia caused by chemotherapy. Except for pegfilgrastim, they are also approved for the mobilization of the peripheral blood progenitor cells.

Drug interactions were called out in the U.S. PI and EU SPC for filgrastim (with lithium and 5-FU) and pegfilgrastim (with 5-FU). Lithium products are oral medications for the treatment of psychiatric patients with bipolar disorder. Lithium has broad effects on the hematopoietic system and is known to increase neutrophil counts from the research of the 1980s. Mechanistically, lithium dose-dependently reduces the levels of surface CXCR4 protein and mRNA in neutrophils.[18] Because CXCR4 protein plays a critical role in the retention of hematopoietic cells within the bone marrow and in their mobilization into the circulation, a reduction in the CXCR4 is associated with an increased release of neutrophils into the circulation. In addition, lithium induces the production of cytokines, including G-CSF, which contributes to the increase in neutrophils.[19] Preliminary evidence from a small number of patients treated concomitantly with filgrastim and 5-fluorouracil indicates

that the severity of neutropenia may be exacerbated, a phenomenon believed to be associated with an increase in the topoisomerase sensitivity in the presence of G-CSF.[20] Furthermore, the product labels indicate that the use of filgrastim or lenograstim is not recommended from 24 h before until 24 h after chemotherapy ends, in view of the sensitivity of rapidly dividing myeloid cells to cytotoxic chemotherapy.

### 14.2.3 Keratinocyte Growth Factor

Marketed globally, palifermin is a truncated, nonglycosylated form of endogenous human keratinocyte growth factor (KGF) with the first 23 *N*-terminal amino acids deleted to improve protein stability. This recombinant KGF contains 140 amino acids (MW 16.3 kDa). It is a mucocutaneous epithelial growth factor and indicated for treatment of oral mucositis in chemotherapy setting. Palifermin has been shown to bind to heparin *in vitro* because KGF is a heparin-binding member of the fibroblast growth factor family,[21–23] and heparin has been shown to be involved in modulating the KGF binding to its receptor.[21] The potential of palifermin binding to low molecular weight heparin was a concern because heparin is used in the indicated clinical setting. As such, its U.S. PI advises against coadministration with heparin and advises to rinse heparin-containing IV lines with saline before administering palifermin into the line. The FDA's approval letter (December 15, 2004) listed three postmarketing-required studies related to drug interactions between palifermin and heparin: an *in vivo* study in healthy subjects to evaluate the drug interaction of palifermin with heparin, an *in vitro* study to evaluate the drug interaction of palifermin with low molecular weight heparins, and an *in vivo* study in healthy subjects, contingent on the results of the *in vitro* study, to evaluate the drug interaction of palifermin with low molecular weight heparins.

Two clinical studies evaluating the interaction between palifermin and heparin were posted on the ClinicalTrials.gov website, presumably to fulfill the postmarketing requirements. The first one was a single-dose study[24] in 27 healthy subjects receiving palifermin (60 μg/kg) coadministered with and without therapeutic levels of un-fractionated heparin. The primary objective was to evaluate the effect of heparin on the PK of palifermin and the secondary objective was to evaluate the effect (activated partial thromboplastin time, aPTT) of a single dose of palifermin on unfractionated heparin pharmacodynamics (PD) based on the PD measures of $AUCaPTT_{0–6}$ and $AUCaPTT_{0–24}$. As reflected in the drug interactions section of the PI, coadministration of heparin resulted in a fivefold increase in AUC and an 80% decrease in the mean clearance rate of palifermin. This case of drug interaction is one of the early examples to challenge the general perception that drug interactions were not of concern when dealing with biologics products. Although the PD results from this same study showed no significant effect of palifermin on heparin activity with respect to aPTT, the clinical impact of the increased palifermin exposure remains to be investigated.

The second study,[25] presumably conducted to further explore the clinical relevance of the observed PK interaction for the palifermin PD effect, was designed to

evaluate the impact of a continuous intravenous (IV) infusion of unfractionated heparin on the multiple-dose pharmacodynamics of palifermin. Forty-four healthy adult subjects were enrolled and randomized into three treatment groups in a ratio of 20 : 15 : 8 receiving either (1) daily palifermin dose of 40 μg/kg for three consecutive days as IV bolus injections and continuous heparin IV infusion, (2) daily palifermin dose of 40 μg/kg for three consecutive days as IV bolus injections, or (3) no treatment (a control group). The PK of palifermin and its PD response were measured, with PD defined as the ratio to baseline of epithelial cell proliferation as assessed by Ki67 staining of buccal mucosal tissue on study day 4. Consistent with the first study, the palifermin exposure was fivefold higher when coadministered with heparin. The PD response was similar with and without heparin, as the geometric mean ratio was 0.863 and the 90% confidence interval was within the predefined interval of 0.7 to 1.43, an equivalence criteria.

Similar to the G-CSF labeling, it is not recommended to administer palifermin within 24 h before or after chemotherapy. Because of the likelihood of coadministration with G-CSF, preclinical studies in murine and nonhuman primate chemotherapy/radiotherapy models explored the possibility of interaction between G-CSF and palifermin and found no evidence of any drug interaction.

### 14.2.4 Thrombopoiesis-Stimulating Agents

Two recombinant thrombopoiesis-stimulating agents (TSAs) are marketed: recombinant human interleukin 11 (rhIL-11) and romiplostim, a thrombopoietin (TPO) mimetic Fc-fusion protein. These recombinant products are indicated for the treatment of thrombocytopenia as their endogenous counterparts play a key role in platelet production.

Romiplostim, produced by recombinant DNA technology in *E. coli*, is a nonglycosylated Fc-peptide fusion protein (peptibody) that has a specific function to increase platelet production via binding to the TPO receptor,[26,27] despite the lack of amino acid sequence homology to the endogenous TPO. By covalent binding of the TPO mimetic peptides to the human immunoglobulin IgG1 Fc domain, this second-generation TSA has prolonged elimination half-life compared to the first-generation product, which failed to reach the market because of the immunogenicity issue.[26,28] No formal drug interaction studies were conducted in the development program, apart from the expected pharmacodynamic interaction with other medications used to treat thrombocytopenia, such as corticosteroids, danazol, azathioprine, intravenous immunoglobulin (IVIG), and anti-D immunoglobulin.

Oprelvekin, a rhIL-11 produced in *E. coli*, is a nonglycosylated protein containing 177 amino acids (MW 19 kDa). It differs from native IL-11 (178 amino acids) in lacking the amino-terminal proline residue. This alteration has not resulted in measurable differences in bioactivity either *in vitro* or *in vivo*. The endogenous IL-11 binds to IL-11 receptors and exerts pleiotropic activities, including stimulation of hemopoiesis, thrombopoiesis, and many nonhematopoietic activities, such as anti-inflammation. In terms of the potential association with the liver metabolic enzymes, IL-11 has been shown to be involved in modulating the transcriptional expression of aromatase in several tissues[29,30] and has minor effect on other hepatic

metabolic enzymes, as shown in the *in vitro* hepatocyte studies.[31] Aromatase is a member of the cytochrome P450 superfamily, which aromatize androgens to form estrogens.[32] Inhibitors of aromatase are clinically used as adjuvants in breast cancer treatment.[32,33] No formal drug interaction studies have been conducted for oprelvekin. Further evaluation of drug interactions related to IL-11 modulation could become important because IL-11 produced by inflammatory cells in the intestine has been implicated in the pathophysiology of cancer, and IL-11 has been proposed as a new target for anticancer therapeutics.[34]

## 14.3 HORMONES

### 14.3.1 Human Growth Hormone

Somatropin is the active ingredient of more than 10 recombinant human growth hormone (rhGH) products approved by the FDA and at least three approved by the EMA. The amino acid sequence of somatropin is identical to that of human growth hormone of pituitary origin, which is a single-chain protein of 191 amino acids (MW 20 kDa), including four cysteine residues present as two intrachain disulfides. They are produced in *E. coli* cells or *Saccharomyces cerevisiae* or mammalian cell line by recombinant DNA technology. Somatropin is indicated for the treatment of growth hormone deficiency, growth failures or short stature due to various causes, and wasting and cachexia secondary to HIV.

Growth hormone has been shown to modulate the cytochrome P450 gene expression and activity in primary culture of human hepatocytes, animal models, and humans.[35–38] It affects the PK of small molecule drugs by which the clearance of some drugs is increased, such as antipyrine and theophylline, and for others decreased, such as amobarbital. Much research is still ongoing to elucidate the precise mechanism of the regulatory effect of growth hormone on various CYP450 enzymes.[39] Consequently the labeling of growth hormone products indicates that monitoring is advisable when it is administered in combination with medicinal products known to be metabolized by CYP450 liver enzymes, such as corticosteroids, sex steroids, anticonvulsants, and cyclosporine. The labeling also advises that patients taking insulin for diabetes mellitus should be carefully monitored during treatment with somatropin because an adjustment of the insulin dose may be required.

On the other hand, the treatment effects of growth hormone can be modulated by the coadministered drugs. Patients with coexisting adrenocorticotropic hormone (ACTH) deficiency should have their glucocorticoid replacement dose carefully adjusted to avoid an inhibitory effect on growth. For women taking oral estrogens, a higher dose of growth hormone may be required to achieve the treatment goal.

***14.3.1.1 Interaction with Glucocorticoid Therapy*** Glucocorticoids may cause growth retardation and reduce the effect of exogenously administered rhGH in GH-deficient patients that appears to be mediated by multiple mechanisms.[40] In a study conducted with seven children who were on prednisone therapy, rhGH was

given to counteract the impaired linear growth. Based on the change in growth velocity, six of seven children responded to rhGH. One patient who received high doses of prednisone (>0.5 mg/kg per day) throughout the rhGH therapy did not experience an increased growth velocity. The response to rhGH was found to be related to the prednisone dose; no increase in growth velocity at prednisone doses >0.35 mg/kg per day was noted, and the response increased with decreased prednisone dose.[41] Downregulation of the expression of GH receptors and the receptor activities, alteration of the GH binding protein, and regulation of the local IGF-1 secretion and activities are a few of the possible mechanisms reported.[40]

Conversely, treatment effects of glucocorticoids are affected by growth hormone because it inhibits 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1), an enzyme that converts inactive cortisone to active cortisol.[42] In patients with GH deficiency, 11β-HSD1 activity is enhanced, which is subsequently normalized after they receive rhGH treatment.[42,43] Hence the U.S. PI of GH products indicate that GH-deficient patients being treated with rhGH may require initiation of glucocorticoid therapy and patients treated with glucocorticoid replacement for previously diagnosed hypoadrenalism may require an increase in their maintenance doses when rhGH therapy is started.

***14.3.1.2 Interaction with Amobarbital*** In a clinical study in children amobarbital was used as a probe to detect hepatic cytochrome P450 enzyme-mediated activity because it is eliminated almost completely through oxidation via hepatic cytochrome P450 mixed-function oxidases. Amobarbital PK after single doses at 3 to 5 mg/kg was compared before and after 6 weeks of rhGH treatment (~2 mg dosed intramuscularly 3 times a week) in four GH-deficient children. The results showed that plasma clearance of amobarbital decreased by 50% after rhGH treatment.[44]

***14.3.1.3 Interaction with Antipyrine*** In a clinical study with GH-deficient adults, the antipyrine clearance test was used as a marker for hepatic cytochrome P450 activity. Antipyrine (10 mg/kg) was given orally before and after 3 months of rhGH therapy in which daily SC doses of rhGH were given at 0.125 IU/kg/week for 1 month followed by daily SC doses at 0.25 IU/kg/week. Median antipyrine clearance increased significantly (by 52%) and antipyrine clearance increased for all subjects except for one, who was a smoker with high baseline clearance.[45]

In another clinical study with 12 GH-deficient children, antipyrine clearance was used to detect short-term and long-term rhGH effect on enzyme activity. Antipyrine (18 mg/kg oral) was given before and after either daily rhGH dose at 1U/day for 5–7 days (short-term effect) or 3 times per week treatment of rhGH at 2U/dose for 6 weeks to 12 months (long-term effect) via intramuscular injection. In both cases, the mean clearance did not change statistically relative to baseline.[46]

***14.3.1.4 Interaction with Theophylline*** In two clinical studies in GH-deficient children, the effect of rhGH on PK of theophylline was assessed.[47] In both studies, 4 mg/kg theophylline was administered (either orally or IV as

aminophylline) before and after 2 IU rhGH given intramuscularly 3 times a week for 3–5 weeks (first study) or 3 weeks (second study). In the first study in four children, the elimination half-life of theophylline decreased by 55% relative to pretreatment (clearance data not reported). In the second study in eight children, even though the half-life did not change, the apparent clearance of theophylline increased by 28% relative to pretreatment.

***14.3.1.5 Interaction with Oral Estrogens*** The effect of oral estrogen therapy on rhGH treatment was demonstrated in eight hypopituitary GH-deficient women with hypogonadism.[48] Daily doses of 2 mg oral estradiol valerate were administered to all subjects for 8 weeks (over 2 estrogen cycles of 4 weeks each). Starting from the second estrogen cycle, subjects received stepwise increase of rhGH daily dose from 0.5 IU in week 1, to 1 IU in week 2, to 2 IU in week 3. The level of insulin-like growth factor 1 (IGF-1) was measured at baseline before estrogen treatment, during the estrogen-alone treatment phase, and during rhGH treatment at the end of weeks 1, 2, and 3 to evaluate the dose-response relationship of rhGH treatment. Orally administered estrogen reduced the IGF-1 level to below the baseline, which was followed by a weekly stepwise increase in IGF-1 levels owing to increasing rhGH dose, indicating a dose response for rhGH treatment. A daily rhGH dose of 1 IU restored the mean IGF-1 level to approximately the baseline level. Therefore, patients who are on oral estrogen therapy will require a higher dose of rhGH for the desired treatment effect. It is important to note that the same study suggested that the antagonistic effect was dose route dependent, because estrogen administered via transdermal patch did not cause a decrease in IGF-1 levels. The differential effect of estrogen from two routes of administration was also demonstrated using other metabolic endpoints for lipid metabolism and protein metabolism. Although the mechanism of this interaction between estrogen and growth hormone is unclear, estrogen has been implicated in modulating the metabolic action of GH *in vitro* as well as in patients.[49,50]

***14.3.1.6 Interaction with Thyroxin*** In a clinical study the effect of rhGH on biomarkers related to thyroxin ($T_4$) therapy (owing to central hypothyroidism) was studied in eight GH-deficient adults.[51] These patients were on stable $T_4$ substitution (0.1–0.2 mg daily dose) for at least 1 year and were studied over four consecutive 4-week periods receiving no rhGH therapy, followed by daily SC doses of 1 IU/m$^2$, then 2 IU/m$^2$, and finally 4 IU/m$^2$ rhGH. At the end of each period, the thyroid hormone levels were measured.

Serum total and free $T_4$ levels decreased with increasing doses of rhGH; however, the decrease was not statistically significant in both cases. Serum total and free triiodothyronine ($T_3$) levels, the active thyroid hormone derived from $T_4$ by deiodinase, increased with increasing doses of rhGH and were significantly greater than no rhGH therapy. The $T_3/T_4$ ratio exhibited a significant dose-dependent increase, and the reverse $T_3$, an inactive isomer of $T_3$ that binds to the thyroid hormone receptor, showed a significant dose-dependent decrease relative to no rhGH dose. In the product label for the GH product Omnitrope it is speculated that in

patients receiving replacement therapy with thyroxin mild hyperthyroidism may occur and the label advises to test thyroid function after starting treatment with rhGH and after dose adjustments.

***14.3.1.7 Interaction with Insulin*** The effect of rhGH on insulin dose-response was studied in six normal male subjects in a crossover design[52] with a 72-h washout in between two treatment occasions in which subjects were started on either 0.45% saline or GH (2 μg/kg/h) 12 h before insulin dose-response studies. During each occasion, subjects were administered insulin doses of 0.4, 1.0, 2.0, and 10.0 mU/kg/min sequentially for 2 h, and each insulin dose was given simultaneously with the infusion of glucose as 50% solution to maintain arterial glucose concentrations at 95 mg/dL. The glucose production and utilization were measured before the first insulin infusion and during the last 40 min of each subsequent insulin infusion. The effect of rhGH on insulin receptor function was also determined before the first insulin infusion by measuring the proportion of monocytes in the mononuclear cell preparation and the insulin binding to the monocytes.

In the presence of rhGH, both dose-response curves of insulin vs. glucose production and insulin vs. glucose utilization shifted to the right—that is, the half-maximal response was significantly increased in the presence of rhGH without affecting the maximum response—suggesting that rhGH increases insulin resistance. Treatment with rhGH did not result in differences in the binding of insulin to the receptors on monocytes. Therefore, the insulin resistance effect was postulated to be the result of a postreceptor defect.

### 14.3.2 Pegvisomant

Pegvisomant (Somavert) is an analog of GH that has been structurally altered to act as a GH receptor antagonist and is indicated for treatment of acromegaly. Pegvisomant is produced in *E. coli* and contains 191 amino acid residues to which several PEG polymers are covalently bound (mostly 4–6 PEG/protein molecule). The predominant molecular weights of pegvisomant are approximately 42, 47, and 52 kDa, with the protein portion being 22 kDa and the PEG being ~5 kDa per unit.

Per the U.S. PI, the treatment regimen for blood sugar control for acromegalic patients with diabetes mellitus who are being treated with insulin and/or oral hypoglycemic agents may require dose reductions after the initiation of therapy with pegvisomant. This is consistent with the report that growth hormone can increase the insulin resistance, as stated in the previous sections.

The effect of growth hormone blockade on insulin sensitivity was studied by Williams *et al.* in seven young adults with type 1 diabetes who were on a combination of short- and long-acting insulins two to four times per day.[53] In this crossover study subjects were given two treatments, either 5 or 10 mg daily SC pegvisomant, over a 3-week period after a run-in period and a 3-week washout in between treatments. At baseline and after each treatment, variable rate insulin infusion was administered overnight to maintain blood glucose at 5 mmol/L. In the morning, this was followed by a two-step hyperinsulinemic euglycemic clamp, using [6,6 $^2H_2$]

glucose and $^2H_5$ glycerol, to measure glucose and glycerol turnover. The investigators showed that overnight insulin requirements significantly decreased for both treatments when compared to baseline. Another study suggested that the decrease in overnight free fatty acid led to an improvement in insulin sensitivity.[54]

The second drug interaction in the U.S. PI stated that in clinical studies patients on opioids often needed higher serum pegvisomant concentrations to achieve appropriate IGF-I suppression compared to patients not receiving opioids. In our literature review, we did not locate any clinical reports of formal drug interaction studies; however, we came across reports of complex interactions between the opioid system and somatostatin, which appears to be an active subject of current research. Morphine and opioid antagonists have been shown to regulate cell growth *in vitro* by interacting with the somatostatin receptors;[55–57] opioids with proliferative effect and opioid antagonists with antiproliferative effect. Analgesic effect associated with octreotide, a peptide analog of somatostatin, administration was reported for a patients treated for acromegaly.[58] The involvement of opioids in regulating the functions and/or secretion of growth hormone has been suggested in clinical setting.[59,60] These research reports were consistent with the advice in the product labeling.

### 14.3.3 Glucagon

Multiple recombinant glucagon products are available commercially in the United States and one is available in the EU. Recombinant glucagon, a single-chain polypeptide hormone with 29 amino acids (MW 3.5 kDa), is synthesized in *E. coli* and is identical to human glucagon produced by the pancreas. Indicated for the treatment of hypoglycemia and also used in diagnostic testing of the stomach and other digestive organs, it increases blood glucose and relaxes smooth muscle of the gastrointestinal tract.

The labeling of glucagon products refer to interactions with various drugs, and most of them are pharmacology-based: Potential interaction with β-blockers might lead to a greater increase in both pulse and blood pressure, which may require therapy in patients with pheochromocytoma or coronary artery disease. When used with indomethacin, glucagon may lose its ability to raise blood glucose or may even produce hypoglycemia. Coadministration with an anticholinergic drug is not recommended owing to increased gastrointestinal side effects. Glucagon may increase the anticoagulant effect of warfarin. Insulin reacts antagonistically toward glucagon. Summarized in the following sections by product are the results of our literature search, which are consistent with the product labeling.

***14.3.3.1 Interaction with Indomethacin and Prostaglandins*** Some prostaglandins have been demonstrated to evoke the release of glucagon from the α-cells in the pancreas.[61] On the other hand, inhibition of the synthesis of prostaglandins by cyclooxygenase inhibitors, such as indomethacin and acetyl salicylic acids, can inhibit the release of glucagon. The effects of indomethacin on glucose levels and on insulin levels were demonstrated in anesthetized male Wistar rats.[62]

The glucose and insulin levels were monitored over 2 h in rats that were administered (1) glucagon only as IV infusion for 120 min, (2) a pretreatment of indomethacin at 10 mg/kg administered intraperitoneally at 15 and 3 h before the infusions of glucagon, or (3) a pretreatment of indomethacin followed by infusions of saline. The basal glucose levels were similar across the three groups. Indomethacin alone does not affect glucose levels or insulin levels over 2 h. In response to glucagon treatment alone, the glucose level and the insulin level increased and remained elevated over 90 min. On the other hand, glucagon treatment in rats pretreated with indomethacin raised the glucose level and the insulin level above baseline for a short time and then declined to below the basal level after 30 min; peak glucose and insulin levels were lower than in rats not administered indomethacin.

In another set of experiments assessing the effect of indomethacin on hepatic glucose output, 2-$^{3}$H-glucose was mixed with normal glucose and infused intravenously for 210 min. At 90 min, which is after establishing steady-state, glucagon was intravenously infused for 120 min either alone or with indomethacin. Results showed that indomethacin reduced both glucose production and glucose utilization.

The same research group conducted a study in conscious female dogs with similar design to evaluate the effect of indomethacin or acetyl salicylic acid on glucagon's ability to produce glucose. Pretreatment with indomethacin and salicylate did not alter basal glucose levels but reduced the effect of glucagon in terms of the increase in glucose levels and the glucose production and utilization.[63]

***14.3.3.2 Interaction with Warfarin*** During 9 months of a study in Massachusetts General Hospital, 469 patients on warfarin were monitored to identify drugs that modify the hypoprothrombinemic effect of warfarin.[64] Twenty-four subjects were on glucagon concomitant therapy. Of these, 13 subjects were on glucagon for at least 2 days with a total dose >50 mg of glucagon. In 8 of these, the hypoprothrombinemic effect of warfarin was enhanced, indicating that they became markedly more sensitive to warfarin during glucagon treatment. They had much prolonged prothrombin time and experienced bleeding while on both warfarin and glucagon. The authors postulated that glucagon may potentiate the anticoagulant action of warfarin by acting synergistically to depress hepatic synthesis of vitamin-K-sensitive clotting proteins or by increasing the affinity of warfarin for its receptor sites.

***14.3.3.3 Interaction with Aminophylline*** Glucagon has myocardial inotropic action in experimental animals and in men. In a study conducted in anesthetized dogs the effect of aminophylline and glucagon when coadministered on coronary and systemic circulation was compared to either agent given alone.[65] Comparisons were made on baseline and posttreatment values of multiple coronary and systemic hemodynamic endpoints, including heart rate, coronary sinus blood flow, cardiac output, and pressures. Treatment with aminophylline alone or glucagon alone was delivered as a constant rate infusion at two different infusion rates, one being half of the other. The combination treatment with aminophylline and glucagon were infused at the lower of two infusion rates for each agent. In total, 21 repeated runs

of the treatment procedures were made in 10 dogs, and summary statistics were determined for various measurements. The average doses used were 2.7 and 5.5 mg/min for aminophylline and 21 and 42 μg/min for glucagon.

When compared to the treatment effect of glucagon alone at the same dose rate, aminophylline enhanced the cardiovascular effects of glucagon. Furthermore, the effects of the glucagon and aminophylline combined treatment were greater than the glucagon treatment effect as a single agent at twice the dose. This interaction was thought to be the result of an accumulation of cyclic 3′,5′-AMP because glucagon activates adenyl cyclase and aminophylline inhibits 3′,5′ nucleotide phosphodiesterase.

## 14.4 CONCLUSIONS

Our literature research had limited success in finding drug interactions that involve the discussed growth factor products, whereas information is more readily available for the covered hormone products. We speculate that the target receptor specificity of these growth factors in combination with the specificity of their postreceptor functions may play a role in the limited findings of drug interactions with these products. The observed interactions are mostly consequences of pharmacological effect of either the perpetrator drug or the victim drug. On the other hand, the hormone products we discussed generally have much broader involvement in biological/physiological functions. They can affect not only the cytochrome P450 enzyme system but also other metabolic functions and enzyme systems in addition to pharmacological interactions mediated at the receptor levels. Furthermore, the complexity of the network of signaling pathways for hormones and the intricate interconnectivities with other complex biochemical signaling processes present opportunities for pharmacodynamic interactions. This can explain the higher volume of available drug interaction information in the literature for hormones as compared to growth factors.

Palifermin is the only case of a PK drug interaction we found in which heparin causes an increase in the palifermin systemic exposure; however, the clinical significance of this interaction is yet to be elucidated. Several cases of PK interactions were reported for recombinant hormone products. Many more cases of pharmacodynamic interactions were observed for both recombinant growth factors and hormones. These reported interactions have clear impact on the clinical use of the products in that they are included in the product labeling whether they are caused by PK alteration or PD modulation.

With the advent of the advanced tools for research at the molecular and cellular level we also expect that the empirically identified drug interactions will gradually find the mechanistic explanations. For instance, lithium's effect on neutrophil count was an empirical finding that was called out in the filgrastim label as a potential interaction. This was later mechanistically attributed to its interaction with the chemokine receptor CXCR4 a few years after the initial approval of filgrastim. As growth factor product pipelines in pharmaceutical development rapidly expand, it is

very likely that drug interactions may become more common for new growth factors that reach the market. We expect that new reports of drug interaction on currently marketed products will be forthcoming as more and more patients take multiple medications given the increasing average age of the population. In summary, our research indicates that investigations on drug interactions for growth factors and hormone products are important for clinical use of these medications and that this is an area for continued investment by scientists in academia, industry, and regulatory agencies.

# DRUG–DRUG INTERACTIONS FOR NUCLEIC ACID-BASED DERIVATIVES

JIAN WANG and HONG ZHAO

## 15.1 INTRODUCTION

In the last decade, oligonucleotide-based therapeutics have been under active development for treatment of diseases such as cancers, genetic disorders, and or infections. Fomivirsen was the first antisense oligonucleotide drug approved by the FDA in 1998 for the treatment of cytomegalovirus retinitis in AIDS patients who have failed therapy with other anticytomegalovirus drugs or who are intolerant or have a contraindication to other therapies. Six years later, pegaptanib (pegylated aptamer), a selective vascular endothelial growth factor (VEGF) antagonist was approved for the treatment of neovascular (wet) age-related macular degeneration (AMD). Both drugs are administered via intravitreal injection.

Antisense oligonucleotides (ASOs) are perhaps the most direct therapeutic strategy to target RNA. Currently ASOs make up the major investigational new drug (IND) submissions for oligonucleotide drug development. These ASOs are designed to bind to the target RNA by well-characterized Watson-Crick base pairing, and once bound to the target RNA, modulate its function through a variety of postbinding events. In this chapter, the primary information used for summarizing drug–drug interactions (DDIs) of oligonucleotides comes from the first- and second-generation ASOs because the currently published DDI studies are mostly focused on these classes of oligonucleotides. When possible, information on other classes of oligonucleotides is presented in the context of these base classes. Caution should be taken in making generalized conclusions based on the limited number of reported studies due to the fact that most of the oligonucleotides are still in the development stage. More information needs to be accumulated to better define the DDI potential between oligonucleotides and other drugs.

This chapter will review the results from both preclinical and clinical DDI studies for the first- and second-generation ASOs. Phosphorothioate ASOs involve substituting sulfur for one of the two nonbridging oxygens in each internucleotide linkage, which are the most extensively studied oligonucleotide drugs and are referred to as first-generation ASOs. MOE-modified ASOs are the products with 2″-*O*-(2-methoxyethyl) (2″-*O*-MOE) ribose sugar modifications for the 4–5 nucleotides at each terminus of ASOs. This modification increases the resistance of ASOs to exonucleases and increases the binding affinity of ASOs to mRNA. The chimeric structure (oligonucleotide core surrounded by MOE-modified nucleotides) as second-generation ASOs preserves their capacity to serve as ribonuclease (RNase) H substrates. The clinical pharmacokinetics (PK) of the first-generation ASOs (single-stranded phosphorothioate modified DNA) and the second-generation ASOs (single-stranded phosphorothioate modified chimeric with partial 2″-*O*-MOE ribose sugar modifications) have been well characterized.

There are very limited reports available for alternative backbone modified oligonucleotides including the chemical classes of peptide nucleic acids (PNAs), locked nucleic acids (LNAs) and morpholino (neutral backbone) nucleic acids (MNAs). The small interfering RNA (siRNA), a double-stranded RNA motif containing both sense and antisense RNA strands, precludes its practical systemic delivery without chemical modification, conjugation or special formulation.[1]

## 15.2 CLINICAL PHARMACOKINETICS

The absorption, distribution, metabolism, and excretion of ASOs have been characterized in clinical trials. Their PK properties largely depend on their physical and chemical properties.

After parenteral administration, the first-generation phosphorothioate oligonucleotides are highly bound to plasma proteins through their hydrophilic sites. The protein binding is >90% for ASOs and >60% for siRNA. The binding of oligonucleotides to plasma proteins limits these compounds from glomerular filtration and urinary excretion. As the degree of protein binding decreases, the amount of free or unbound oligonucleotides increases, leading to an increase in urinary excretion. Oligonucleotides distribute rapidly from blood to tissues with a distribution half-life less than 2 h. They highly accumulate in tissues such as kidney, liver, spleen, lymph nodes, adipocytes, and bone marrow. Oligonucleotides do not cross the blood–brain barrier and poorly distribute to muscle, heart, and lung. Oligonucleotides are metabolized by nucleases ubiquitously expressed in tissue cells. The elimination half-life of oligonucleotides reflects the metabolism in tissues, the equilibration of drugs and metabolites between tissues and blood, and excretion by the kidneys.[2]

Chemical modifications of oligonucleotides result in marked difference in their PK profiles.[3] The first-generation ASOs modify the phosphodiester backbone of DNA to a phosphorothioate backbone, which enhances their hydrophobicity and protein binding and increases their nuclease resistance. The 2″-*O*-MOE modification at the 5″ and 3″ termini for the second-generation ASOs blocks the exonuclease

**FIGURE 15-1** Chemical modifications. Solid circle: phosphorothioate modification; dotted circle: 2′-methoxyethyl modification

cleavage and therefore they are primarily cleared by slow endonuclease digestion and ultimate excretion of parent drug and metabolites in urine. Figure 15-1 illustrates modification sites of oligonucleotides to produce the first- and second-generation ASOs.

While the terminal elimination half-lives for the first-generation ASOs are <40 h, the second-generation ASOs have longer half-lives up to a month, which allow for a less frequent (once weekly or longer interval) dosing regimen as compared to the first-generation ASOs. Many of the advantages associated with moving from the first-generation to second-generation ASOs are directly related to their improved PK profiles.[1]

The oligonucleotides that lack charge and/or have low binding to plasma proteins are prone to rapid clearance from plasma, with substantially high excretion in urine in the first day after administration, resulting in less overall tissue accumulation and ultimate low target bioavailability. This phenomenon is seen in the classes of PNAs, morpholinos, and unmodified siRNA. The PK properties of unmodified RNAi oligonucleotides preclude systemic delivery. Therefore chemical conjugation or formation approaches, such as pegylation or lipoidal delivery systems are often needed to improve the RNAi stability and distribution into target tissues.

## 15.3 DRUG–DRUG INTERACTIONS

### 15.3.1 *In Vitro* Studies

***15.3.1.1 DDI via Protein Binding Replacement*** Oligonucleotides are highly bound to plasma proteins, which protects them from urinary excretion and

subsequently increases their plasma exposure. Albumin has been identified as one of the major plasma proteins with high binding capacity to oligonucleotides. The binding of oligonucleotides to plasma proteins is relatively weak with low dissociation constant of 5–20 μmol/L, and the binding sites for this hydrophilic drug class differ from the binding sites for hydrophobic small molecular drugs. Therefore, it is speculated that the potential for PK interactions mediated by protein binding is expected to be low at clinically relevant concentrations. Several *in vitro* and clinical studies have been reported in the literature regarding the protein binding displacement for oligonucleotide-based drugs. Three examples are provided.

ISIS 113715 is a 20-mer first-generation ASO that is complementary to the protein tyrosine phosphatase 1B (PTP-1B) messenger RNA and subsequently reduces translation of the PTP-1B protein, a negative regulator of insulin receptor. ISIS 113715 is currently being studied in early Phase II clinical trials to determine its ability to improve or restore insulin receptor sensitivity in patients with type 2 diabetes mellitus. *In vitro* protein binding displacement studies in human plasma samples showed minor effects on rosiglitazone and no effect on glipizide when co-incubated with ISIS 113715.[4]

ISIS 301012 (mipomersen) is a 20-nucleotide second-generation ASO targeting human ApoB mRNA. Its protein binding is >95% at clinically relevant concentrations. An *in vitro* protein binding interaction study with atorvastatin and simvastatin (both with >95% protein binding) showed no displacement between mipomersen sodium and atorvastatin or simvastatin at clinically relevant plasma concentrations.[5,6]

ISIS 2302, a first-generation ASO that targets human intercellular adhesion molecule-1 (ICAM-1) mRNA, is currently in clinical development for treatment of ulcerative colitis.[7] *In vitro* drug displacement studies with ISIS 2302 and other highly protein-bound drugs, including warfarin, salicylic acid, valproic acid, tolbutamide, acetylsalicylic acid, ibuprofen, and prednisone, were conducted. The results suggest that coadministration of ISIS 2302 with these highly protein-bound drugs did not displace one another at supraclinical plasma concentrations. Based on these findings, it is not anticipated to see PK interactions in the clinical settings as a result of the displacement of plasma protein binding.

In summary, *in vitro* data from protein binding displacement studies suggest that the potential for PK interactions caused by displacement of plasma protein binding is low when ASOs are administrated concomitantly with other highly protein bound drugs. The analyses by Benet et al. have shown that changes in plasma protein binding usually do not influence the clinical exposure of a patient to a drug.[8] As a consequence, no adjustments in dosing regimens will be necessary except in rare cases of a drug with a high extraction ratio and narrow therapeutic index that is given parenterally or, even rarer, a drug with a narrow therapeutic index that is given orally and has a very rapid pharmacokinetic-pharmacodynamic equilibration time.[8]

***15.3.1.2 DDI via Metabolic Enzymes*** Oligonucleotides are mainly metabolized by nucleases and are unlikely substrates for the cytochrome P450 (CYP) mediated oxidative metabolism. Therefore, the PK of oligonucleotides are not expected to be affected by concomitant use of drugs that are CYP inducers or

inhibitors. However, the potential for oligonucleotides to act as inhibitors or inducers of CYP enzymes cannot be precluded. *In vitro* studies using human microsomes have shown that several oligonucleotide drugs inhibited multiple CYP enzymes, including CYP3A4, CYP1A2, CYP2D6, CYP2E1, CYP2B6, CYP2A6, and CYP2C8 (unpublished data).

Several studies with negative results are reported in literature. For example, the ability of mipomersen to inhibit the major CYP enzymes—namely CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4—in cryo-preserved human hepatocytes was evaluated.[6] The results of this *in vitro* study revealed <10% inhibition in the activity of all evaluated enzymes at concentrations up to 800 μg/mL (~100 μmol/L), and dose-dependent inhibition was not observed. This study suggested mipomersen is unlikely to be an inhibitor of CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4.

### 15.3.2 DDI Studies in Animals

G3139 is a first-generation ASO targeting the open reading frame of oncogene *Bcl-2* mRNA. The PK interaction between G3139 and anthracycline anticancer drug doxorubixin was studied in severely compromised immunodeficient (SCID) mice model bearing human breast cancer xenografts.[9,10] When doxorubixin was coadministrated intravenously with intraperitoneal (IP) G3139, elevated G3139 peak concentration ($C_{max}$) was observed, with a fourfold increase in the absorption rate of G3139 from the IP cavity into plasma in the presence of doxorubixin. The systemic exposure (AUC) was only slightly increased.[10]

It is interesting that examination of the exposure of doxorubixin after coadministration with G3139 revealed marked elevation of tumor doxorubixin levels as compared to those after doxorubixin administered alone. Although the plasma exposure of doxorubixin in mice treated with G3139 was minimally reduced compared with no G3139 treatment, tumor exposure to doxorubixin increased twofold to threefold, indicating possible oligonucleotide-drug interactions at the tumor site. The mechanism behind the observed elevation of tumor tissue distribution is not fully understood. Findings from histology slides suggest that it could be through enhancing drug permeability of tumor tissue treated with G3139, thereby increased tumor uptake of doxorubixin-G3139 complexes that could form in the circulation, and increased binding of doxorubixin to tumor cells arising from G3139-induced DNA lesions caused by apoptosis activation.[10]

Similar findings have been reported by Wang et al. for an antisense anti-MDM2 mixed-backbone oligonucleotide, which is a second-generation ASO.[11] There were increased tissue levels of irinotecan and its active metabolite SN-38 in nude xenograft mice models when the two drugs were given in combination.[11]

### 15.3.3 DDI Studies in Humans

Two ASOs, fomivirsen and pegaptanib have been approved in the United States in 1998 and 2004, respectively. Two early clinical studies conducted for pegaptanib

alone and in combination with photodynamic therapy (PDT) or verteporfin showed no apparent difference in the plasma PK of pegaptanib.[12] However, no dedicated DDI studies have been conducted in humans between either of these two ASOs and other drugs.

A number of oligonucleotide-based drugs are currently on clinical trials. For the drugs that are in the development stage, a number of clinical DDI studies have been reported in the literature. An overview of the effects of oligonucleotides on the PK of coadministrated drugs is presented in Table 15-1. The effects of coadministrated small molecular drugs on the PK of oligonucleotides are summarized in Table 15-2. Some of these DDI studies and their study designs tailored based on the PK characteristics of individual drugs are further discussed in the following section. Among them, there are a few formal or dedicated DDI studies. The approach of a cross-study comparison was also used in several studies. A literature search found that the published DDI studies conducted in humans were to assess the potential interactions between first-generation or second-generation ASOs and other chemical drugs that are either in combination therapies with these ASOs, or are likely to be coadministrated to patients.

***15.3.3.1 Mipomersen (ISIS 301012)*** Mipomersen is being developed as an adjunct to maximally tolerated lipid-lowering therapies in patients with familial hypercholesteromia who have severely elevated low-density lipoprotein cholesterol (LDL-C) and are at high risk for coronary heart disease. A dedicated DDI study was conducted to characterize the PK interactions between mipomersen and lipid-lowering agents, including simvastatin and ezetimibe.[6] Both drugs and their metabolites are highly protein bound (> 90%). In addition, simvastatin is a substrate of CYP3A4 and CYP2D6, and ezetimibe is primarily metabolized via glucuronide conjugation with subsequent biliary and renal excretion. In this study, 10 healthy subjects per cohort received an oral dose of 40 mg simvastatin or 10 mg ezetimibe before and after four 2-h intravenous doses of 200 mg mipomersen sodium over an 8-day period. For cohort A, mipomersen sodium was given on days 4, 6, 8, and 11. Mipomersen PK profiles were assessed after the dose on day 8 (mipomersen alone) and on day 11 (in combination with simvastatin). For cohort B, mipomersen sodium was given on days 8, 10, 12, and 15. Mipomersen PK profiles were assessed after the dose on day 12 (mipomersen alone) and on day 15 (in combination with ezetimibe). The dosing regimen for mipomersen sodium was designed to achieve near steady-state tissue accumulation by the end of dosing.

The values for area under the plasma concentration-time curve ($AUC_{24h}$), maximum plasma concentration ($C_{max}$), and apparent elimination half-life ($t_{½}$) of each drug were calculated, and their 90% confidence intervals (CIs) of the geometric least-squares means (GLSM) ratios are shown in Table 15-3, which indicates that the systemic exposure of mipomersen was not altered when coadministered with simvastatin or ezetimibe. However, mipomersen coadministration resulted in approximately 50% lower $C_{max}$ and 28% higher $AUC_{24\,h}$ for simvastatin; and a 42% lower $C_{max}$ with no appreciable change in $AUC_{72\,h}$ for ezetimibe. The underlying mechanisms for the observed results are to be elucidated.

**TABLE 15-1 Effects of Oligonucleotides on the Pharmacokinetics of Other Drugs**

| Interacting ASOs | Class | Substrates | Study Design | PK Parameters | Results | References |
|---|---|---|---|---|---|---|
| Mipomersen | Gen 2 | Ezetimibe, simvastatin | Healthy subjects; parallel design | $AUC_{72\,h}$, $AUC_{24\,h}$, $C_{max}$, $T_{max}$, $t_{½}$ | Ezetimibe $C_{max}$ ↓ 42%, $AUC_{72h}$ no change; simvastatin $C_{max}$ ↓ 49%, $AUC_{24h}$, ↑ 28% | 5,6 |
| ISIS 113715 | Gen 1 | Glipizide, metformin, rosiglitazone | Cancer patients; sequential crossover design | $AUC_{24\,h}$, $C_{max}$, $t_{½}$ | Rosiglitazone $C_{max}$ ↑ 46%, $AUC_{24}$ ↑ 15%; glipizide and metforminno change | 4 |
| ISIS 2503 | Gen 1 | Gemcitabine | Cancer patients; sequential crossover design | $C_{ss}$ | Gemcitabine $C_{max}$ ↓, AUC ↓; not statistically significant | 13 |
| ISIS 3521 | Gen 1 | 5-fluorouracil | Cancer patients; sequential crossover design | $C_{ss}$ | No changes | 14 |
| | | Gemcitabine, cisplatin | Cancer patients; sequential crossover design | AUC, $C_{max}$ | No changes | 15 |
| | | Paclitaxel, carboplatin | Cancer patients; sequential crossover design | AUC, $C_{max}$ | No changes | 16,17 |

| | | $AUC_{24\,h}$ (h·ng/mL) | 1.00 | (0.94, 1.07) |
| Mipomersen | Ezetimibe | $C_{max}$ (ng/mL) | 1.05 | (0.86, 1.28) |
| | | $AUC_{24\,h}$ (h·ng/mL) | 1.01 | (0.92, 1.11) |

[a] $n = 10$.
CI: confidence interval; PK: pharmacokinetics.

The clinical trial design used in this study took into consideration the long elimination half-life of mipomersen and the relatively large interindividual variability in the PK of the oral lipid-lowering drugs. Thus the design of the study included a loading dose approach for mipomersen sodium that ensured achievement of near steady-state concentrations in the target tissues (the liver and kidneys) before testing of potential interactions with concomitantly administered oral lipid-lowering agents. The sequential design allowed each individual in the study to be his or her own control to reduce intraindividual variability. The limitation of the study is that a 24-h PK sampling duration was too short relative to the 30-day elimination half-life of mipomersen; therefore the $AUC_{0-24\,h}$ may not be an appropriate parameter for assessing the effect of coadministered drugs on the PK of mipomersen.

ISIS 2503 is an ASO targeting H-ras mRNA. The potential PK interaction between ISIS 2503 and gemcitabine was evaluated in a Phase I trial.[13,21] A total of 19 patients were treated with a fixed dose of gemcitabine 1000 mg/m$^2$ on days 1 and 8 and two escalating doses of ISIS 2503 (4 and 6 mg/kg/day) as a 14-day continuous infusion starting on day 1. An additional 8 patients received a flat dose of ISIS 2503 based on their ideal body weight. Blood samples for gemcitabine PK were collected on day 1 (gemcitabine alone) and day 8 (with ISIS 2503). Only steady-state concentration ($C_{ss}$) data were collected for ISIS 2503, at pregemcitabine and postgemcitabine infusion on day 8.

At three dose levels studied, the $C_{ss}$ of ISIS 2503 achieved during infusion were not altered, and the fraction of total oligonucleotide composed of parent oligonucleotide (intact 20-mer ISIS 2503) was also unchanged when ISIS 2503 was coadministered with gemcitabine. There was a consistent decrease in the gemcitabine plasma concentration observed at the end of the 30-min gemcitabine infusion in all ISIS 2503 three dose cohorts. Alteration of gemcitabine concentration at this single time point resulted in a 31–48% decrease in mean AUC and a 49–57% decrease in mean $C_{max}$ in patients receiving a flat dose or 6 mg/kg/day of ISIS 2503.

ISIS 113715 is a 20-mer first-generation phosphorothioate ASO that is complementary to the protein tyrosine phosphatase 1B (PTP-1B) mRNA. In a clinical DDI study, 23 healthy subjects received a single oral dose of an antidiabetic drug (either metformin 500 mg, glipizide 5 mg or rosiglitazone 2 mg) alone and together with 200 mg of ISIS 113715 subcutaneously in a sequential-crossover design.[4] The results of this study indicated that there were no large deviations outside of the boundaries of 80–125% for PK parameters ($C_{max}$ and AUC) of glipizide and metformin, but some differences were observed for rosiglitazone with the mean ratios and 90% CIs for $C_{max}$ and $AUC_{24\,h}$ of 1.46 (1.04–2.05) and 1.15 (0.80–1.65), respectively when coadministered with ISIS 113715. Conversely, there were no observed significant alterations in the PK of ISIS 113715 when administered in combination with these oral antidiabetic drugs.

#### *15.3.3.2 ISIS 3521 (LY900003)*

*In Combination with 5-Fluorouracil and Leucovorin* ISIS 3521 (LY900003) is a sodium salt form of a 20-mer phosphorothioate oligonucleotide that hybridizes to the 3′-untranslated region of human protein kinase C (PKC) mRNA and inhibits its expression through RNase-mediated cleavage of hybridized PKC mRNA. In a clinical study, patients with refractory solid tumors received ISIS 3521 as a 21-day continuous infusion simultaneously with 5-fluorouracil (5-FU) and leucovorin given daily for 5 days and repeated every 4–5 weeks (one cycle).[14] A PK analysis for 5-FU and ISIS 3521 was performed on samples taken during the first cycle in all patients. Fifteen patients received ISIS 3521 at one of three dose levels: 1.0 mg/kg/day ($n = 3$), 1.5 mg/kg/day ($n = 3$), and 2.0 mg/kg/day ($n = 9$). All patients concomitantly received 5-FU (425 mg/m$^2$/day) and leucovorin (20 mg/m$^2$/day) for 5 consecutive days. The washout time period was not specified in the paper. The steady-state plasma concentration ($C_{ss}$) of ISIS 3521 without 5-FU was determined by averaging the measured plasma concentrations at time 24 h to time 21 days during the continuous infusion. After 5-FU administration on day 4, ISIS 3521 concentrations measured at multiple time points within 90 min of 5-FU administration were averaged to obtain $C_{ss}$.

The plasma concentration of ISIS 3521 increased in a dose-dependent manner over the range of doses investigated. There was no significant difference in the ISIS 3521 steady-state plasma concentrations when ISIS 3521 was given with or without 5-FU. Furthermore, there was no significant change in the percentage of intact ISIS 3521 in the presence or absence of 5-FU. Because there were only two to three patient observations recorded in each dose treatment cohort, a statistical test cannot be performed with confidence; however, on visual inspection of the data, there was considerable overlap of the ISIS 3521 $C_{ss}$ values in the presence and absence of 5-FU. The PK parameters [AUC, $t_{½}$, CL, and volume of distribution at steady-state ($V_{ss}$)] of 5-FU in the presence or absence of ISIS 3521 also showed no evidence for PK interactions.[14]

*In Combination with Cisplatin and Gemcitabine* A clinical trial of ISIS 3521 in combination with cisplatin/gemcitabin was conducted in patients with advanced

non–small cell lung cancer.[15] The PK interaction study design was similar to the previously mentioned study reported by Mani et al. For gemcitabine, the respective GLSM ratios on study days 1 and 8 for each parameter of interest ($AUC_{0-\infty}$ and $C_{max}$) were ranged from 0.69 to 1.27. Similar findings were observed for cisplatin, and the GLSM ratios for each parameter of interest in cycles 1 and 2 were close to 1.

This study compared the $C_{ss}$ of ISIS 3521 and total oligonucleotide in the absence and presence of gemcitabine, cisplatin, or both drugs. In the presence of gemcitabine, the GLSM ratio for $C_{ss}$ of ISIS 3521 and total oligonucleotide are 0.81 and 0.70, respectively. In the presence of cisplatin, the GLSM ratio for $C_{ss}$ of ISIS 3521 and total oligonucleotide are 1.60 and 1.61, respectively. The clinical significance of this magnitude of change in ISIS 3521 $C_{ss}$ when coadministered with gemcitabine and cisplatin is unknown.

*In Combination with Carboplatin and Paclitaxel* A clinical trial was conducted with ISIS 3521 in combination with carboplatin and paclitaxel for the treatment of patients with non-small cell lung cancer. Patients initially received carboplatin (target AUC: 5 or 6 mg/mL/min) and paclitaxel (175 mg/m$^2$) alone in cycle 1. In cycle 2 and beyond, patients received escalating doses of ISIS 3521 (1.0–2.0 mg/kg/day) by continuous intravenous infusion on days 1–14, with carboplatin and paclitaxel administered on day 4. In the expanded phase, all patients received carboplatin (target AUC: 6 mg/mL/min) and paclitaxel (175 mg/m$^2$) with ISIS 3521 (2.0 mg/kg/day) starting in cycle 1. Treatment was repeated every 21 days until maximum benefit. There was no evidence of a PK interaction between ISIS 3521 and either chemotherapy agent.[16]

Overall, these literature reports conclude that ISIS 3521 has no clinically relevant effect on the PK of those drugs administered concomitantly with ISIS 3521. However, a 60% increase in ISIS 3521 $C_{ss}$ in the presence of cisplatin was observed and the underlying mechanisms are not fully explained. In addition, there are several limitations for these reported DDI studies. Firstly, some of the analyses did not include other PK parameters such as $C_{max}$ which was limited by the design of DDI studies. Secondly, the studies suffered from a small numbers of patients (e.g., only two to three patient observations recorded in each dose cohort in the study with 5-FU and leucovorin). Lastly, the dose and regimen in these studies may not be the maximal clinical doses to detect a significant PK interaction.

*Drug Transporters* Despite over a decade of research, the mechanism of cellular membrane transport of oligonucleotide-based drugs are still unclear, possibly involving multiple pathways.[22] Oligonucleotides usually have molecular weight greater than 4 kDa and contain more than 12 negative charges per molecule. The general belief is that only lipophilic or small hydrophilic molecules can traverse biological membranes. The mechanism of cellular uptake of naked DNA/RNA is still poorly defined, but one of these pathways may require a cell membrane transporter in mammalian cells.[23]

There are no published reports on the role of P-glycoprotein (P-gp) in oligonucleotide absorption or intracellular transport. A study suggested that at a high

dose of 10 μM, an ASO can be transported by P-gp *in vitro* (unpublished data). Until the mechanism of oligonucleotide transport is clearly delineated, the potential for oligonucleotides to be as substrates of transporters such as P-gp should be considered during the drug development.

## 15.4 OTHER CONSIDERATIONS

### 15.4.1 Indirect Effects on CYP Enzymes

Some oligonucleotides contain unmethylated CpG motifs within the oligonucleotide sequence that have been shown to be potent immune stimulators.[24] The immunostimulatory oligonucleotides can activate signaling cascades to regulate the expression of a number of host-defense proteins such as interferons and interferon-inducible genes. Cytokines, such as interleukin 6 (IL-6), may affect the oxidative metabolic process by modulating the hepatic microsomal CYP isozymes, and thereby change the metabolism of concomitantly administrated drugs that are substrates of these enzymes.

The delivery systems and formulations of oligonucleotides, which include conjugation with other molecules, such as pegylation, liposome, or lipid nanoparticles (LNPs) are often used to extend elimination half-lives of the siRNA or ASOs or to have a better delivery of them to the target cells. Some delivery systems or formulations may have the ability to modulate cytokine release and increase the complexities of drug interaction potential.

### 15.4.2 Immunogenicity and Its Effects on PK

Experimental induction of antibodies in mice suggests the potential for DNA to be immunogenic. In normal subjects, anti-DNA B cell precursors make up as much as 1–5% of the total B cell population. The introduced antisense DNA or RNA may induce autoantibody or anti-ASO antibody production (immunogenicity) that would not normally occur for the endogenous sense sequence. There are several mechanisms that may be responsible for the incidence of ASO immunogenicity: (1) the use of modified analogs designed to increase nuclease resistance may cause immunogenicity, (2) protection from digestion and enhanced cellular uptake achieved by linking oligonucleotides to protein carriers causes additional problems, and (3) some oligonucleotide drugs produce potent immune stimulation *in vivo*, thereby enhancing the anti-PEG antibody response when these immunostimulatory agents are encapsulated in PEGylated liposomes.[25,26]

Altered PK profiles associated with antiproduct antibody formation have been seen in therapeutic biological products. The potential for immunogenicity of oligonucleotide-based drugs may also alter their PK. Currently most of the oligonucleotide-based drugs are still in the preclinical or early clinical development stages; therefore, the immunogenicity data are not available for most compounds under development.

### 15.4.3 Considerations of DDI Studies

The first-generation ASOs often need to be administrated chronically to attain persistent modulation of target gene expression, especially in oncology. When both the substrate and the interacting drug are likely to be given over an extended period of time, the often used DDI study design is to administer the substrate to steady state with collection of blood samples over one or more dosing intervals followed by multiple dose administration of an interacting drug.[27] The second-generation ASOs have long elimination half-life of 10–30 days. Design of the DDI studies for such long half-life drugs may consider inclusion of a loading dose to ensure faster achievement of the steady-state concentrations of the study drug. In addition, a cross-over design may not be practical because of the long elimination half-life.

### 15.4.4 Regulatory Perspective

Currently, there is no specific regulatory guidance on clinical pharmacology studies for oligonucleotide-based drugs. The current regulatory recommendations for evaluation of oligonucleotide drug–drug interactions are similar to the approaches for small molecule drugs.[27] In general, the metabolism and transport of an investigational new drug and its interactions with other drugs as a substrate, inhibitor, or inducer needs to be assessed during drug development as part of an adequate assessment of the drug's safety and effectiveness. At the early stage of clinical development, *in vitro* screens need to be conducted to determine if the parent or active metabolite(s) is a substrate, inhibitor or inducer of CYP isozymes or P-gp transporter. These studies will help determine the need for *in vivo* drug–drug interactions.

In oncology, many oligonucleotides are developed in combination with the current standard therapeutics. If oligonucleotides are to be used in combination with other drugs such as chemotherapy, the potential for a PK drug–drug interaction between oligonucleotides and the drugs in the combination will need to be evaluated during the development of such combination therapy. The evaluation can be conducted in a dedicated drug–drug interaction trial or incorporated in a clinical efficacy and safety trial. This evaluation is important because many oncology drugs have narrow therapeutic indices and altered drug systemic exposure could increase drug-related toxicities or compromise its therapeutic effects.

## 15.5 SUMMARY

The reported clinical data suggest that there are limited PK drug–drug interactions between oligonucleotide-based drugs and small molecular drugs. A few animal studies demonstrated that tumor exposures of the anticancer drugs are affected by the oligonucleotides coadministration without affecting their plasma pharmacokinetics. *In vitro* data from protein binding displacement studies suggest that the

potential for pharmacokinetic interactions caused by displacement of plasma protein binding is low when oligonucleotides are administrated concomitantly with other highly protein-bound drugs.

Oligonucleotides are mainly metabolized by nucleases in tissues and are unlikely to be substrates of CYP metabolic enzymes. However, the current data regarding the CYP enzyme involvement are very limited and cannot exclude the possibility that the exposure of oligonucleotides can be affected by CYP enzyme inducers or inhibitors. Given that *in vitro* studies using human microsomes have shown that several oligonucleotide drugs inhibited multiple CYP enzymes, the inhibition and induction potential of oligonucleotides for CYP enzymes should be addressed during the oligonucleotide-based drug development.

# MONOGRAPHS FOR DRUG-DRUG INTERACTIONS OF THERAPEUTICS BIOLOGICS

JOCELYN LEU, SIMONE KASEK, CHRISTINE LI, WARARAT LIMOTHAI, DORA BABU MADHURA, CHETAN RATHI, SUMIT RAWAL, JOSIAH RYMAN, MARGARET THOMSON, ASHIT TRIVEDI, HONGHUI ZHOU, and BERND MEIBOHM

Over the last decade, the unprecedented increase in the clinical use of therapeutic biologics for a variety of indications including immune-mediated inflammatory disease indications such as rheumatoid arthritis and inflammatory bowel diseases, and oncology indications has resulted in a new class of drug-drug interactions, therapeutic biologic-drug interactions. However, this kind of drug-drug interactions is generally understudied or underreported due to a perception that drug-drug interactions involving therapeutic biologics are scarce and of limited relevance. Moreover, the underlying mechanisms of many of those drug-drug interactions are still poorly understood.

In order to better assess the landscape of drug-drug interactions for therapeutic biologics, we have compiled drug-drug interaction monographs involving therapeutic biologics either as victims or perpetrators based on current US labeling information and scientific literature. To broaden our knowledgebase in this area, our monographs also include some important 'theoretical' drug-drug interactions with well established plausible mechanisms. In order to make those monographs more useful to the readers, we have also included other relevant references if available from which the drug-drug interaction contents was obtained. We feel these monographs might be useful for readers as they might guide expectations in what might be encountered as potential therapeutic biologic-drug interaction in clinical development programs and applied pharmacotherapy.

**Drug-Drug Interaction Monograph for ACCRETROPIN (Somatropin) #1**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Somatropin/Accretropin, Bio-Tropin, |
| Class/Molecular weight: | Hormone/~22 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Cortisone, prednisone |
| Class/Molecular weight: | Corticosteroids |

**Description of the effect of the DDI:**
Inhibits metabolism of corticosteroids to the biologically active metabolites (e.g., cortisone to cortisol).

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Inhibits 11 β-hydroxysteroid dehydrogenase type 1 (11βHSD-1) in adipose/hepatic tissue since conversion of these agents to the biologically active metabolites is dependent on the activity of the 11βHSD-1.

**Clinical consequences:**
Patients treated with glucocorticoid replacement therapy for previously diagnosed hypoadrenalism may require an increase in their maintenance or stress doses.

**Reference:** Accretropin prescribing information

**Drug-Drug Interaction Monograph for ACCRETROPIN (Somatropin) #2**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Somatropin/Accretropin, Bio-Tropin |
| Class/Molecular weight: | Hormone/~22 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | CYP450 3A4 substrates |
| Class/Molecular weight: | Corticosteroids, sex steroids, anticonvulsants, cyclosporine |

**Description of the effect of the DDI:**
Potentially increases clearance of CYP450 3A4 substrates.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Increases CYP450-mediated antipyrine clearance. These data suggest that somatropin administration may alter the clearance of compounds known to be metabolized by CYP450 liver enzymes (e.g., corticosteroids, sex steroids, anticonvulsants, cyclosporine). No formal DDI studies have been conducted.

**Clinical consequences:**
Careful monitoring is advisable.

**Reference:** Accretropin US prescribing information

Lee JI, Zhang L, Men AY, Kenna LA, Huang SM. CYP-mediated therapeutic protein-drug interactions: clinical findings, proposed mechanisms and regulatory implications. Clin Pharmacokinet. 2010 May;49(5):295–310.

**Drug-Drug Interaction Monograph for ACCRETROPIN (Somatropin) #3**

**Perpetrator drug:**
INN name/US brand name: Somatropin/Accretropin
Class/Molecular weight: Hormone/~22 kDa

**Victim drug:**
INN name/US brand name: Insulin and oral antidiabetic agents
Class/Molecular weight: Hormone/5.8 kDa

**Description of the effect of the DDI:**
Pharmacodynamic effect inducing insulin resistance.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Decreases insulin sensitivity at high doses. Growth hormone induces insulin resistance by the stimulation of lipolysis and a concomitant switch from oxidation of glucose to oxidation of lipids, during both acute and chronic treatment.

**Clinical consequences:**
This could lead to glucose intolerance and possibly diminish the effects of insulin. The dose of insulin and/or oral agents may require adjustment when somatropin therapy is initiated.

**Reference:**

**Drug-Drug Interaction Monograph for ACCRETROPIN (Somatropin) #4**

**Perpetrator drug:**
INN name/US brand name: Glucocorticoids
Class/Molecular weight: Small Molecule

**Victim drug:**
INN name/US brand name: Somatropin/Accretropin
Class/Molecular weight: Hormone/~22 kDa

**Description of the effect of the DDI:**
Pharmacodynamic effect on growth promoting effects of somatropin.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Excessive glucocorticoid therapy may attenuate the growth promoting effects of somatropin in children.

**Clinical consequences:**
Carefully adjust glucocorticoid replacement therapy with concomitant growth hormone.

**Drug-Drug Interaction Monograph for ACTEMRA (Tocilizumab) #1**

---

**Perpetrator drug:**
INN name/US brand name: Methotrexate
Class/Molecular weight: Small Molecule/476 Da

**Victim drug:**
INN name/US brand name: Tocilizumab/Actemra
Class/Molecular weight: Monoclonal Antibody/~148 kDa

**Description of the effect of the DDI:**
No effect on tocilizumab clearance by coadministered methotrexate evaluated by population PK analysis.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
None.

**Reference:** Actemra US prescribing information

---

**Drug-Drug Interaction Monograph for ACTEMRA (Tocilizumab) #2**

---

**Perpetrator drug:**
INN name/US brand name: NSAIDS
Class/Molecular weight: Small Molecule

**Victim drug:**
INN name/US brand name: Tocilizumab/Actemra
Class/Molecular weight: Monoclonal Antibody/~148 kDa

**Description of the effect of the DDI:**
No effect on tocilizumab clearance by coadministered NSAIDS evaluated by population PK analysis.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
None.

**Reference:** Actemra US prescribing information

Frey N, Grange S, Woodworth T. Population pharmacokinetic analysis of tocilizumab in patients with rheumatoid arthritis. J Clin Pharmacol. 2010 Jul;50(7):754–66.

**Drug-Drug Interaction Monograph for ACTEMRA (Tocilizumab) #3**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Corticosteroids |
| Class/Molecular weight: | Small Molecule |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Tocilizumab/Actemra |
| Class/Molecular weight: | Monoclonal Antibody/~148 kDa |

**Description of the effect of the DDI:**
No effect on tocilizumab clearance by coadministered corticosteroids evaluated by population PK analysis.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
None.

**Reference:** Actemra US prescribing information

Frey N, Grange S, Woodworth T. Population pharmacokinetic analysis of tocilizumab in patients with rheumatoid arthritis. J Clin Pharmacol. 2010; 50(7):754–66.

**Drug-Drug Interaction Monograph for ACTEMRA (Tocilizumab) #4**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Tocilizumab/Actemra |
| Class/Molecular weight: | Monoclonal Antibody/~148 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Simvastatin/Zocor |
| Class/Molecular weight: | Small Molecule/419 Da |

**Description of the effect of the DDI:**
In 12 RA patients not treated with Actemra, receiving 40 mg simvastatin, exposures of simvastatin and its metabolite, simvastatin acid, was 4- to 10-fold and 2-fold higher, respectively, than the exposures observed in healthy subjects. One week following administration of a single infusion of Actemra (10 mg/kg), exposure of simvastatin and simvastatin acid decreased by 57% and 39%, respectively, to exposures that were similar or slightly higher than those observed in healthy subjects. Exposures of simvastatin and simvastatin acid increased upon withdrawal of Acemtra in RA patients.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Simvastatin is a CYP3A4 and OATP1B1 substrate. *In vitro* data suggested that IL-6 reduced mRNA expression for CYP3A4, and this reduced expression was reversed by co-incubation with tocilizumab at clinically relevant concentrations. Accordingly, inhibition of IL-6 signaling in RA patients treated with tocilizumab may restore CYP3A4 activity to higher levels than those in the absence of tocilizumab leading to increased metabolism of drugs that are CYP3A4 substrate.

*(Continued)*

**Clinical consequences:**
Selection of a particular dose of simvastatin in RA patients should take into account the potentially lower exposures that may result after initiation of Actemra (due to normalization of CYP3A4) or higher exposures after discontinuation of Actemra.

---

**Drug-Drug Interaction Monograph for ACTEMRA (Tocilizumab) #5**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Tocilizumab/Actemra |
| Class/Molecular weight: | Monoclonal Antibody/~148 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Omeprazole/Prilosec |
| Class/Molecular weight: | Small Molecule/345 Da |

**Description of the effect of the DDI:**
In RA patients receiving 10 mg omeprazole, exposure to omeprazole was approximately 2 fold higher than that observed in healthy subjects. In RA patients receiving 10 mg omeprazole, before and one week after Actemra infusion (8 mg/kg), the omeprazole $AUC_{inf}$ decreased by 12% for poor (N = 5) and intermediate metabolizers (N = 5) and by 28% for extensive metabolizers (N = 8) and were slightly higher than those observed in healthy subjects.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Omeprazole is a CYP2C19 and CYP3A4 substrate. *In vitro* data suggested that IL-6 reduced mRNA expression for several CYP450 isoenzymes including CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6 and CYP3A4, and this reduced expression was reversed by co-incubation with tocilizumab at clinically relevant concentrations. Accordingly, inhibition of IL-6 signaling in RA patients treated with tocilizumab may restore CYP450 activities to higher levels than those in the absence of tocilizumab leading to increased metabolism of drugs that are CYP450 substrates.

**Clinical consequences:**
None specifically mentioned for omeprazole.

---

**Drug-Drug Interaction Monograph for ACTEMRA (Tocilizumab) #6**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Tocilizumab/Actemra |
| Class/Molecular weight: | Monoclonal Antibody/~148 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Dextromethorphan/Robitussin, Delsym |
| Class/Molecular weight: | Small Molecule/271 Da |

**Description of the effect of the DDI:**
In 13 RA patients receiving 30 mg dextromethorphan, exposure to dextromethorphan was comparable to that in healthy subjects. However, exposure to its metabolite, dextrorphan (a CYP3A4 substrate), was a fraction of that observed in healthy subjects. One week following administration of a single infusion of Actemra (8 mg/kg), dextromethorphan exposure was decreased by approximately 5%. However, a larger decrease (29%) in dextrorphan levels was noted after Actemra infusion.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Dextromethorphan is a CYP2D6 and CYP3A4 substrate. *In vitro* data suggested that IL-6 reduced mRNA expression for several CYP450 isoenzymes including CYP1A2, CYP2B6, CYP2C9, CYP2C19, CYP2D6 and CYP3A4, and this reduced expression was reversed by co-incubation with tocilizumab at clinically relevant concentrations. Accordingly, inhibition of IL-6 signaling in RA patients treated with tocilizumab may restore CYP450 activities to higher levels than those in the absence of tocilizumab leading to increased metabolism of drugs that are CYP450 substrates.

**Clinical consequences:**
None specifically mentioned for dextromethorphan.

**Drug-Drug Interaction Monograph for ACTIMMUNE (Interferon Gamma-1B)**

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Interferon Gamma-1B/Actimmune |
| Class/Molecular weight: | Polypeptide/~17 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | CYP450 substrates |
| Class/Molecular weight: | Small Molecule |

**Description of the effect of the DDI:**
Depression of hepatic metabolism.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Preclinical studies in rodents demonstrated a decrease in hepatic microsomal CYP450 concentrations.

*(Continued)*

**Clinical consequences:**
None mentioned.

**Reference:**

Actimmune prescribing information

---

**Drug-Drug Interaction Monograph for ADCETRIS (Brentuximab vedotin) #1**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Brentuximab vedotin/Adcetris |
| Class/Molecular weight: | Antibody-drug conjugate/~153 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Midazolam or other CYP3A4 substrates |
| Class/Molecular weight: | Small molecule/326 Da |

**Description of the effect of the DDI:**
Co-administration of Adcetris did not affect exposure to midazolam, a CYP3A4 substrate. Monomethyl auristatin E (MMAE) does not inhibit other CYP enzymes at relevant clinical concentrations. Adcetris is not expected to alter the exposure to drugs that are metabolized by CYP3A4 enzymes.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
None.

**Clinical consequences:**
None mentioned.

**Reference:**
Adcetris prescribing information

---

**Drug-Drug Interaction Monograph for ADCETRIS (Brentuximab vedotin) #2**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Ketoconazole/Nizoral |
| Class/Molecular weight: | Small molecule/531 Da |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Brentuximab vedotin/Adcetris |
| Class/Molecular weight: | Antibody-drug conjugate/~153 kDa |

**Description of the effect of the DDI:**
Co-administration of Adcetris with ketoconazole, a potent CYP3A4 inhibitor, increased exposure to MMAE by approximately 34%.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Adcetris is a CD30-directed antibody-drug conjugate (ADC) consisting of three components: 1) the chimeric IgG1 antibody cAC10, specific for human CD30, 2) the microtubule

disrupting agent monomethyl auristatin E (MMAE), and 3) a protease-cleavable linker that covalently attaches MMAE to cAC10. MMAE is primarily metabolized by CYP3A.

**Clinical consequences:**
Patients who are receiving strong CYP3A4 inhibitors concomitantly with Adcetris should be closely monitored for adverse reactions.

**Reference:**
Adcetris prescribing information

---

**Drug-Drug Interaction Monograph for ADCETRIS (Brentuximab vedotin) #3**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Rifampin/Rifadin, Rimactane |
| Class/Molecular weight: | Small molecule/823 Da |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Brentuximab vedotin/Adcetris |
| Class/Molecular weight: | antibody-drug conjugate/~153 kDa |

**Description of the effect of the DDI:**
Co-administration of Adcetris with rifampin, a potent CYP3A4 inducer, reduced exposure to MMAE by approximately 46%.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Adcetris is a CD30-directed antibody-drug conjugate (ADC) consisting of three components: 1) the chimeric IgG1 antibody cAC10, specific for human CD30, 2) the microtubule disrupting agent monomethyl auristatin E (MMAE), and 3) a protease-cleavable linker that covalently attaches MMAE to cAC10. MMAE is primarily metabolized by CYP3A.

**Clinical consequences:**
None mentioned.

**Reference:**
Adcetris prescribing information

---

**Drug-Drug Interaction Monograph for AMEVIVE (Alefacept)**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Alefacept/Amevive |
| Class/Molecular weight: | Fc fusion protein/91.4 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | CYP450 substrates |
| Class/Molecular weight: | Small molecule |

**Description of the effect of the DDI:**
No drug interaction studies have been conducted.

*(Continued)*

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
The formation of CYP450 enzymes may be suppressed by increased levels of cytokines (e.g., TNFα, IL-1, IL-6, IL-10, IFN) during chronic inflammation. Therefore, a molecule that exerts its pharmacological effect by inhibiting the release of cytokines, such as Amevive, could normalize the formation of CYP450 enzymes.

**Clinical consequences:**
Upon initiation or discontinuation of Amevive in patients being treated with CYP450 substrates with a narrow therapeutic index, monitoring of the effect (e.g., warfarin) or drug concentration (e.g., cyclosporine or theophylline) is recommended and the individual dose of the drug product may be adjusted as needed.

**Reference:**
Amevive prescribing information

Lee JI, Zhang L, Men AY, Kenna LA, Huang SM. CYP-mediated therapeutic protein-drug interactions: clinical findings, proposed mechanisms and regulatory implications. Clin Pharmacokinet. 2010 May;49(5):295–310.

---

**Drug-Drug Interaction Monograph for ANGIOMAX (Bivalirudin)**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Bivalirudin/Angiomax |
| Class/Molecular weight: | Peptide/2.2 kDa |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Anti-coagulants (e.g., heparin, warfarin, thrombolytics, glycoprotein IIb/IIIa-receptor inhibitors (GPI)) |
| Class/Molecular weight: | Small Molecule |

**Description of the effect of the DDI:**
In clinical trials in patients undergoing Percutaneous Coronary Intervention (PCI) or Percutaneous Transluminal Coronary Angioplasty (PTCA), co-administration of Angiomax with heparin, warfarin, thrombolytics, or GPIs was associated with increased risks of major bleeding events compared to patients not receiving these concomitant medications.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Bivalirudin is a direct thrombin inhibitor used as an anticoagulant. Thus use with other anticoagulants can increase the risk of bleeding events.

**Clinical consequences:**
None mentioned in label.

**Reference:**
Angiomax prescribing information

Kastrati A, Neumann FJ, Mehilli J et al: Bivalirudin versus unfractionated heparin during percutaneous coronary intervention. N Engl J Med (2008) 359 (7/Aug 14): 688–96.

---

**Drug-Drug Interaction Monograph for APIDRA, HUMULIN, HUMALOG, NOVOLOG, LANTUS (Insulin) #1**

**Perpetrator drug:**

INN name/US brand name: Oral antidiabetic products
Class/Molecular weight: Small molecule

**Victim drug:**

INN name/US brand name: Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc
Class/Molecular weight: Hormone/~5.8 kDa

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia. Insulin may be used as adjunctive therapy with oral antihyperglycemic agents when glycemic control deteriorates on oral antidiabetic agents in patients with type 2 diabetes mellitus. However lower daily doses of insulin are required to maintain desirable glycemic control.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Both drugs reduce blood glucose.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring

**Reference:**
Apidra prescribing information, Humulin prescribing information, Humalog prescribing information, Lantus prescribing information, Novolog prescribing information

Kabadi MU, Kabadi UM. Efficacy of sulfonylureas with insulin in type 2 diabetes mellitus. Ann Pharmacother. 2003 Nov;37(11):1572–6.

**Drug-Drug Interaction Monograph for APIDRA, HUMULIN, HUMALOG, NOVOLOG, LANTUS (Insulin) #2**

**Perpetrator drug:**

INN name/US brand name: Pramlintide/Symlin
Class/Molecular weight: Peptide/4 kDa

**Victim drug:**

INN name/US brand name: Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc
Class/Molecular weight: Hormone/~5.8 kDa

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia. Pramlintide is used as an adjunct to insulin and has been associated with an increased risk of insulin-induced severe hypoglycemia, particularly in patients with type 1 diabetes.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Both drugs reduce blood glucose.

*(Continued)*

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring. To minimize the risk of insulin-induced hypoglycemia, all patients should reduce premeal insulin by 50% upon initiation of pramlintide therapy, monitor blood glucose frequently, and contact their healthcare provider if symptoms of nausea and/or hypoglycemia are persistent. Careful patient selection, patient instruction, and insulin dose adjustments are critical for reducing the risk of hypoglycemia.

| Class/Molecular weight: | Hormone/~5.8 kDa |

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia. A nested case-control study was performed with diabetic patients treated with insulin or with oral antidiabetic drugs, who were admitted to hospital with hypoglycemia. Hypoglycemia was significantly associated with current use of ACE inhibitors (odds ratio 2.8 [95% CI 1.4–5.7]). In another nested case-control study, hypoglycemia was associated with the use of ACE inhibitors (odds ratio [OR] 3.2, 95% CI 1.2–8.3, $P = 0.023$),

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Insulin resistance appears to be a syndrome that is associated with a clustering of metabolic disorders, including non-insulin-dependent diabetes mellitus, obesity, hypertension, lipid abnormalities, and atherosclerotic cardiovascular disease. Thus if a facet of metabolic disorders is normalized, this may perhaps increase insulin sensitivity

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc |
| Class/Molecular weight: | Hormone/~5.8 kDa |

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia. Case reports describe disopyramide-induced hypoglycemia as well as hypoglycemia on disopyramide treatment with concomitant insulin.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Both drugs have the potential to cause hypoglycemia.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring

## Drug-Drug Interaction Monograph for APIDRA, HUMULIN, HUMALOG, NOVOLOG, LANTUS (Insulin) #5

**Perpetrator drug:**

INN name/US brand name: Fibrates (e.g. clofibrate, gemfibrozil, fenofibrate)
Class/Molecular weight: Small molecule

**Victim drug:**

INN name/US brand name: Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc
Class/Molecular weight: Hormone/~5.8 kDa

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia. In a case report where the patient added gemfibrozil to her medications, the patient experienced recurrent hypoglycemic episodes concurrant with a massive reduction in insulin requirements.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Insulin resistance appears to be a syndrome that is associated with a clustering of metabolic disorders, including non-insulin-dependent diabetes mellitus, obesity, hypertension, lipid abnormalities, and atherosclerotic cardiovascular disease. Thus if a facet of metabolic disorders is normalized, this may perhaps increase insulin sensitivity.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring.

**Reference:**

Apidra prescribing information, Humulin prescribing information, Humalog prescribing information, Lantus prescribing information, Novolog prescribing information.

## Drug-Drug Interaction Monograph for APIDRA, HUMULIN, HUMALOG, NOVOLOG, LANTUS (Insulin) #6

**Perpetrator drug:**

INN name/US brand name: Fluoxetine/Prozac
Class/Molecular weight: Small molecule/309 Da

**Victim drug:**

INN name/US brand name: Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc
Class/Molecular weight: Hormone/~5.8 kDa

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia. Fluoxetine treatment was associated with a large decline in HbA1c and insulin levels in obese diabetics compared to placebo. Fasting glucose levels also declined significantly.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Serotonergic antidepressants appear to enhance insulin sensitivity, reduce hyperglycemia and facilitate the storage of glucose as glycogen in muscle tissue.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring.

**Reference:**
MA Deeg and EW Lipkin. Hypoglycemia associated with the use of fluoxetine. West J Med. 1996 March; 164(3): 262–263.

**Drug-Drug Interaction Monograph for APIDRA, HUMULIN, HUMALOG, NOVOLOG, LANTUS (Insulin) #7**

---

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Monoamine oxidase inhibitors (e.g. hydralazine, phenelzine) |
| Class/Molecular weight: | Small molecule |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc |
| Class/Molecular weight: | Hormone/~5.8 kDa |

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia. Depressed subjects responding to monoamine oxidase inhibitor (MAOI) therapy displayed a decrease in peak glucose concentration, a lower fasting blood glucose level and shorter duration of the hyperglycemic period after the administration of glucose ($p < 0.05$).

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
MAOIs are associated with hypoglycemia.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring.

**Reference:**

|---|---|
| INN name/US brand name: | Salicylates (e.g. aspirin) |
| Class/Molecular weight: | Small molecule |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc |
| Class/Molecular weight: | Hormone/~5.8 kDa |

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Salicylates lower blood sugar and enhance glucose-stimulated insulin secretion in normal and diabetic subjects. Although the hypoglycemic effect appears to be mediated by enhanced insulin secretion, extrapancreatic mechanisms cannot be excluded. The mechanism of the enhanced insulin secretion appears to be mediated by prostaglandin synthesis inhibition.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring.

## Drug-Drug Interaction Monograph for APIDRA, HUMULIN, HUMALOG, NOVOLOG, LANTUS (Insulin) #11

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Somatostatin analogs/(see Accretropin) |
| Class/Molecular weight: | Hormone |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc |
| Class/Molecular weight: | Hormone/~5.8 kDa |

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia. Infusion of somatostatin (combined deficiency of glucagon and growth hormone) accentuated insulin-induced hypoglycemia (plasma glucose nadir: 36+/−2 ng/dl during infusion of somatostatin vs. 47+/−2 mg/dl in control studies, $P < 0.01$) and impaired restoration of normoglycemia (plasma glucose at min 90: 73+/−3 mg/dl at end of somatostatin infusion vs. 92+/−3 mg/dl in control studies, $P < 0.01$).

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Impaired recovery of plasma glucose was due to blunting of the compensatory increase in glucose appearance since glucose disappearance was not augmented, and was attributable to suppression of glucagon secretion.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring.

**Reference:**
Rizza R, Cryer P, and Gerich J. Role of glucagon, catecholamines, and growth hormone in human glucose counterregulation. J Clin Invest. 1979;64: 62–71.

## Drug-Drug Interaction Monograph for APIDRA, HUMULIN, HUMALOG, NOVOLOG, LANTUS (Insulin) #12

**Perpetrator drug:**

| | |
|---|---|
| INN name/US brand name: | Sulfonamide antibiotics |
| Class/Molecular weight: | Small molecule |

**Victim drug:**

| | |
|---|---|
| INN name/US brand name: | Insulin/Apidra, Humulin, Humalog, Novolog, Lantus, etc |
| Class/Molecular weight: | Hormone/~5.8 kDa |

**Description of the effect of the DDI:**
Pharmacodynamic interaction: Drugs that may increase the blood glucose-lowering effect of insulins can increase the risk of hypoglycemia.

**Description of the (proven, putative or hypothesized) mechanism of the DDI:**
Because of their structural similarities to sulfonylureas, sulfonamides are liable to facilitate hypoglycemia by increasing insulin release in susceptible individuals.

**Clinical consequences:**
May require insulin dose adjustment and particularly close monitoring.
